Regional poison control centers have developed management guidelines for ethylene glycol toxicity and can provide management advice at 800-222-1222. Key recommendations suggest that a patient with symptoms of ethylene glycol poisoning or in whom self-harm, misuse, or potentially malicious administration is a possibility should be referred to an emergency department immediately regardless of the dose reported. Conversely, the absence of symptoms shortly after ingestion does not exclude a potentially toxic dose and should not be used as a triage criterion. Inhalation exposures do not develop into systemic toxicity and can be managed out-of-hospital if the patient is asymptomatic. Patients with clinically significant mucous membrane irritation should be referred for evaluation. Decontamination of dermal exposures should include routine cleansing with mild soap and water. Removal of contact lenses and immediate irrigation with room temperature tap water is recommended for ocular exposures. If symptoms of eye injury are present, ophthalmologic consultation or follow-up may be helpful. Adults who ingest a “swallow” or children who ingest more than a witnessed taste or lick, or if the amount is unknown, of most ethylene glycol products should be referred immediately to an emergency department for evaluation. Gastrointestinal decontamination with ipecac syrup, gastric lavage, or activated charcoal is not recommended.  

Three treatment goals exist for patients with methanol or ethylene glycol toxicity: (1) correction of metabolic acidosis with bicarbonate; (2) ADH enzyme blockade, which inhibits the metabolism of methanol and ethylene glycol to toxic metabolites; and (3) removal of the parent alcohol and its metabolites by hemodialysis. The acidic metabolites of methanol and ethylene glycol can cause a profound bicarbonate-resistant metabolic acidosis, with several hundred milliequivalents of excess acid produced per hour. In contrast to lactic acid, these acids are not metabolized to bicarbonate, and massive amounts of bicarbonate may be necessary merely for partial correction of the acidosis. Early correction of metabolic acidosis may be beneficial in reversing methanol-induced visual impairment, most likely related to the induction of a larger fraction of dissociated formic acid, which should decrease the amount of formic acid entering the CNS. Depending on the severity of the patient’s acidosis, IV bicarbonate can be administered by intermittent boluses, an initial bolus followed by an infusion, or infusion alone. Boluses of 1 to 2 mL/kg to attain a target serum pH of 7.45 to 7.50 followed by an infusion of 150 mEq/L of sodium bicarbonate in 5% dextrose at 1.5 to 2 times the maintenance fluid rate are suggested. With ethylene glycol, the potential for worsened hypocalcemia during the administration of large amounts of sodium bicarbonate should be considered.

To prevent further production of the toxic and acidic metabolites of methanol and ethylene glycol, metabolism of the parent compounds by the enzyme ADH must be blocked by either ethanol or fomepizole (Antizol). After significant toxic alcohol exposure, ADH blockade should be carried out in any adult or child with symptoms or with methanol or ethylene glycol levels greater than 20 mg/dL, even if asymptomatic. If ethanol is used to block ADH, the goal is to maintain the blood ethanol level between 100 and 150 mg/dL, which completely saturates ADH. The affinity of ADH for ethanol is 10 to 20 times greater than for methanol and 100 times greater than for ethylene glycol. When methanol or ethylene glycol metabolism is blocked by ethanol, their half-lives increase to more than 30 hours or 17 hours, respectively. Prevention of methanol and ethylene glycol metabolism by ethanol explains the delayed toxicity seen in patients who ingest ethanol in combination with either of these substances. When dosing ethanol, it also is important to measure the patient’s initial blood ethanol level. If it is greater than 100 mg/dL, a loading dose is unnecessary, and the patient can be started on a maintenance infusion (Table 153-1). The required maintenance dose of ethanol may nearly triple during hemodialysis because ethanol also is efficiently removed. Ethanol may be given orally or intravenously. Potential side effects of IV administration include CNS and respiratory depression, hypotension, vomiting, hypoglycemia, and thrombophlebitis, although even in children, adverse effects are limited. Oral ethanol loading may be associated with gastritis. Initial close monitoring of serum ethanol and glucose levels every 1 to 2 hours is essential until a steady-state level of 100 to 150 mg/dL is achieved. Levels should be checked every 2 to 4 hours thereafter. Monitoring of ethanol therapy ideally is accomplished in the intensive care unit.

Similar to ethanol, fomepizole blocks the metabolism of methanol and ethylene glycol by ADH and prevents the formation of toxic metabolites. When methanol or ethylene glycol metabolism is blocked by fomepizole, their half-lives increase to an average of 52 and 17 hours, respectively. Fomepizole is a pregnancy category C drug; although not approved for use in children, its use has been reported. Potential advantages of the use of fomepizole rather than

*a Specific gravity = 0.79.  
*b Equivalent to 86 proof undiluted liquor (34 g ethanol/dL).  
*c Equivalent to 7.9 g ethanol/dL.  
*d Assumes initial ethanol concentration is zero; dose is independent of chronic drinking status.  
ethanol include ease of administration, predictable pharmacokinetics, improved patient safety profile, a standardized and less complicated dosing regimen that does not require direct observation or frequent blood monitoring, longer duration of action, and lack of CNS depression. Nonetheless, simply blocking toxic alcohol metabolism does not alter the toxicity of preformed metabolites. The use of either fomepizole nor ethanol supplants the need for hemodialysis. The main disadvantage of the use of fomepizole is its acquisition cost. The dose is 15 mg/kg followed by 10 mg/kg every 12 hours for four doses. After five doses, the dose increases to 15 mg/kg every 12 hours until the ethylene glycol concentration is undetectable or less than 20 mg/dL, and the patient is asymptomatic with a normal arterial pH. Dosing changes are required during hemodialysis. Side effects of fomepizole include headache, nausea, dizziness, inflammation at the site of infusion, rash, eosinophilia, and mild, reversible transaminase elevation. To date, no clinical trials have compared the relative efficacy, safety, or cost of fomepizole and ethanol in the treatment of ethylene glycol or methanol toxicity.

Rapid removal of the methanol or ethylene glycol through hemodialysis before they have been metabolized remains the cornerstone of therapy. In addition, hemodialysis, preferably using a dialysate high in bicarbonate, corrects acidosis and uremia, aids in fluid management and cardiovascular stabilization, and removes the toxic metabolites in late presenters. Hemodialysis decreases the half-life of methanol and ethylene glycol to 2.5 to 3.5 hours. Peritoneal dialysis and hemoperfusion are much less effective. Indications for hemodialysis in patients with methanol or ethylene glycol toxicity are controversial. In general, however, hemodialysis is indicated in patients who have metabolic acidosis, renal compromise, visual symptoms (methanol), deterioration despite intensive supportive care, or electrolyte imbalance unresponsive to conventional therapy. Indications for hemodialysis are generally for patients who have metabolic acidosis, renal insufficiency, deterioration despite intensive care, electrolyte disturbance, or visual disturbances with methanol. In addition, a blood level of either substance greater than 50 mg/dL usually calls for dialysis, but in patients with normal kidneys, prolonged fomepizole treatment alone has been used without hemodialysis. For ethylene glycol, a glycolic acid level greater than 8 mmol/L, an anion gap greater than 20 mmol/L, or an initial pH less than 7.50, predicts renal failure and the need for hemodialysis. Methanol and ethylene glycol levels should be interpreted in the context of the clinical status and the time after ingestion. An acidic patient with a low blood level after a delayed presentation requires more aggressive treatment than an asymptomatic patient with a high level.

The endpoint for hemodialysis is an undetectable serum ethylene glycol or methanol concentration and the disappearance of acid-base abnormalities and signs of systemic toxicity. Closure of the anion gap also may serve as an endpoint for hemodialysis in situations in which levels are not available or reliable (i.e., in patients with delayed presentation).

In methanol poisoning, the rate of the final degradation reaction of formic acid to carbon dioxide and water depends on the cofactor folate in primates (see Fig. 153-1). Studies in animals and limited human data suggest that formate metabolism is enhanced with the use of folate. Accordingly, 50 mg of leucovorin (folinic acid) should be given IV every 4 hours to adults with methanol toxicity. Likewise, the cofactors thiamine and pyridoxine have theoretical benefit based on their use in humans with primary hyperoxaluria, although no clinical trials have studied their efficacy in the treatment of ethylene glycol toxicity. Adequate cofactor levels minimize oxalic acid production by favoring the production of other, less toxic metabolites (see Fig. 153-2). Because underlying deficiencies of these vitamins may not be readily apparent in patients, empirical administration is reasonable. The recommended adult doses are folic acid, 100 mg IV every 6 hours, and pyridoxine, 50 mg every 6 hours for 2 days. With symptomatic hypocalcemia, IV calcium should be supplemented, albeit cautiously, to avoid further precipitation of calcium oxalate crystals in tissues. Asymptomatic hypercalcemia need not be treated. Magnesium is a cofactor along with thiamine for the detoxification of glycolic acid and should be replaced in patients who are deficient.

Disposition

Admission is generally necessary for patients undergoing treatment for ethylene glycol or methanol exposure. In addition, all patients with clinical or laboratory findings consistent with these ingestions should be admitted, even when the history is lacking or unavailable. Early consultation with a nephrologist for possible hemodialysis is necessary in the management of suggested toxic alcohol ingestion. If such services are not available, the patient should be given an ADH inhibitor and transferred to a setting where dialysis is available. A regional poison center or medical toxicologist may be contacted to guide management. An ophthalmologist can evaluate visual injury fully in patients with methanol poisoning. Neurologic consultation and follow-up monitoring of patients with either methanol or ethylene glycol toxicity are prudent given the potential for delayed or persistent neurologic sequelae.

Prevention

The addition of the bittering agent denatonium benzoate (Bitrex) to consumer automotive products containing 10% or more ethylene glycol or 4% or more methanol has been implemented. The effect of this effort has not yet been demonstrated to decrease exposure to these products in children. Another opportunity for prevention is the substitution of less toxic glycols, such as propylene glycol, into commercial antifreeze.

ISOPROPYL ALCOHOL

Perspective

Isopropyl alcohol (isopropanol) is a clear, colorless liquid with a slightly bitter taste. It is the second most commonly ingested alcohol after ethanol. In 2006, the American Association of Poison Control Centers reported 21,181 isopropanol exposures: 88% were unintentional, and 3% involved moderate or major effects; there were 4 fatalities. Rubbing alcohols, which contain 70 to 91% isopropanol or ethanol, are frequent sources of exposure and may be tinted green or blue. Other sources include skin and hair products, nail polish removers, disinfectants, window and pine household cleaners, and antifreeze. Children experience toxicity most commonly from accidental ingestion, but inhalation and transdermal absorption during sponge bathing may occur. Isopropanol and its major metabolite acetone cause twice the CNS depression of ethanol, so intentional ingestion as an alcohol substitute is encountered frequently in adults. Isopropanol is not associated with the toxicity of ethylene glycol or methanol poisoning, and death after exposure is rare. The typical fatality involves a chronic, older alcoholic with mixed ethanol-isopropanol intoxication after a drinking binge.
Absorption of isopropanol is rapid and complete; 80% of a dose is absorbed within 30 minutes of ingestion. The kidneys excrete 20% as unchanged isopropanol. A small portion is resecreted into the stomach and saliva; the remaining 80% is metabolized in the liver to acetone by ADH (Fig. 153-3). Acetone is excreted primarily by the kidneys, with small amounts expired through the lungs.

Isopropanol blood levels peak 30 minutes to 3 hours after ingestion, and elimination follows first-order kinetics, with a half-life of 3 to 7 hours. In children, the half-life may be slightly shorter. Acetone is eliminated more slowly, with a half-life of 22 hours. The rate of elimination of isopropanol may be increased by chronic ethanol abuse and decreased by hepatic damage. A potentially lethal dose in adults is 150 to 200 mg/dL. In large doses, isopropanol causes hypotension from peripheral vasodilation and direct myocardial depression. Topical effects include corneal de-epithelialization or dermal burns, described in premature infants as a result of skin de-esterification. Acetone does not seem to be shunted into the formation of acetoacetate or β-hydroxybutyrate; the finding of ketosis without acidosis is characteristic of isopropanol ingestion. No pathognomonic postmortem features are seen in isopropanol intoxication. Pulmonary congestion at autopsy is seen in finding of ketosis without acidosis is characteristic of isopropyl alcohol as a CNS depressant, and it has been suggested that coma may be prolonged by the extended elimination of this metabolite. The extent to which acetone contributes to coma is brought into question by the report of a patient who was awake and conversant, with acetone levels of 200 mg/dL. In large doses, isopropanol causes hypotension from peripheral vasodilation and direct myocardial depression. Topical effects include corneal de-epithelialization or dermal burns, described in premature infants as a result of skin de-esterification. Acetone does not seem to be shunted into the formation of acetoacetate or β-hydroxybutyrate; the finding of ketosis without acidosis is characteristic of isopropanol ingestion. No pathognomonic postmortem features are seen in isopropanol intoxication. Pulmonary congestion at autopsy is nonspecific and typical of deaths involving drug-induced CNS depression.

Clinical Findings

Clinically, gastrointestinal and CNS complaints predominate. Intoxication may be suggested by apparent inebriation with the odor of acetone rather than ethanol detected on the breath. The patient may have headache or dizziness and may exhibit neuromuscular incoordination, confusion, and nystagmus. Severe ingestions may result in deep coma, which is prolonged compared with ethanol. Respiratory depression or failure may occur. Patients may have a loss of deep tendon, corneal, or protective airway reflexes and have an extensor response to plantar reflex testing. Pupillary size varies, but miosis is most common. Isopropanol is a gastrointestinal irritant; the patient may complain of abdominal pain, nausea, and vomiting. Gastritis can occur with dermal and oral exposure.

Pathophysiology

Isopropanol is a potent CNS depressant, but the mechanism of action is unclear. Acetone is also a CNS depressant, and it has been found that coma may be prolonged by the extended elimination of this metabolite. The extent to which acetone contributes to coma is brought into question by the report of a patient who was awake and conversant, with acetone levels of 200 mg/dL. In large doses, isopropanol causes hypotension from peripheral vasodilation and direct myocardial depression. Topical effects include corneal de-epithelialization or dermal burns, described in premature infants as a result of skin de-esterification. Acetone does not seem to be shunted into the formation of acetoacetate or β-hydroxybutyrate; the finding of ketosis without acidosis is characteristic of isopropanol ingestion. No pathognomonic postmortem features are seen in isopropanol intoxication. Pulmonary congestion at autopsy is nonspecific and typical of deaths involving drug-induced CNS depression.

Pupillary size varies, but miosis is most common. Isopropanol is a gastrointestinal irritant; the patient may complain of abdominal pain, nausea, and vomiting. Gastritis can occur with dermal and oral exposure.

Pupillary size varies, but miosis is most common. Isopropanol is a gastrointestinal irritant; the patient may complain of abdominal pain, nausea, and vomiting. Gastritis can occur with dermal and oral exposure.

Hematemesis and upper gastrointestinal bleeding stem from gastritis, but are not commonly reported.

Hypotension, although rare, signifies severe poisoning, with a mortality rate of 45%. One case series found mortality only when coma and hypotension were present. Sinus tachycardia is common, but other atrial and ventricular dysrhythmias are rare and generally found only with confounding hypoxia, acidosis, or shock. Hypothermia is frequent. Rarely, myoglobinuria, acute tubular necrosis, hepatic dysfunction, and hemolytic anemia have been reported. Metabolic acidosis is not present with isopropanol intoxication unless accompanied by hypotension, gastrointestinal bleeding, or co-ingestants; this is a distinguishing clinical feature. Hyperglycemia may be noted, but hypoglycemia has not previously been described, even though it should be sought in patients who have altered mental status.

Diagnostic Strategies

Useful laboratory tests for evaluating a patient with isopropanol ingestion include an isopropanol level, serum electrolytes, BUN, creatinine, osmolality, serum and urine ketones, and arterial blood gas analysis. Peak isopropanol levels occur soon after ingestion, whereas acetone levels peak later at 4 hours after ingestion. The most common laboratory abnormality is ketosis with little or no acidosis and normal blood glucose levels. The ketosis is from the metabolite acetone, which can be detected in the blood 15 minutes after ingestion and in the urine 3 hours after ingestion. Acetone is uncharged, so it does not elevate the anion gap. Isopropanol and acetone contribute to the increased osmol gap. In theory, a 1-mg/dL increase in blood isopropyl alcohol concentration should result in a 0.17-mOsm/kg increase in serum osmolality.

One early laboratory clue to the diagnosis of isopropanol ingestion is “pseudo-renal failure,” or isolated false elevation of creatinine with a normal BUN. This condition results from interference of acetone and acetoacetate by the colorimetric method of creatinine determination. Creatinine is expected to increase 1 mg/dL for every 100 mg/dL of acetone. A CK level should be checked because patients with isopropanol toxicity may have coma-induced myoglobinuria and rhabdomyolysis.

Differential Considerations

Patients who ingest significant amounts of isopropanol appear intoxicated or have depressed consciousness, and the differential diagnosis includes all of the causes of altered mental status in an alcoholic patient, as discussed previously. The presence of ketosis warrants a search for diabetic ketoacidosis, alcoholic ketoacidosis, salicylism, cyanide, or starvation ketosis. A distinguishing feature of isopropanol ingestion is the presence of ketosis without acidosis. An increased osmolar gap with acidosis mandates a search for other toxic alcohols. In the setting of a high or rising creatinine and normal BUN, acute rhabdomyolysis also should be considered. Other substances that falsely elevate creatinine are cimetidine, nitroethane, and nitrates, often mixed with methanol in formulating radio-controlled vehicle fuel. Detection of isopropanol in acetonemic patients not exposed to isopropanol (i.e., the conversion of acetone to isopropanol in vivo) is well described.

Management and Disposition

Neither gastric emptying nor activated charcoal administration is warranted. The patient should be intubated if unable to protect the airway, if intubation is indicated on the basis of co-ingestants, or if the patient's mental status is poor and
deteriorating. In contrast to methanol and ethylene glycol, ADH blockade with ethanol or fomepizole is not indicated. Hypotension should be managed with fluids and vasopressors as needed. If the patient remains hypotensive or has further vital sign deterioration despite these measures, dialysis is indicated. Some authors also recommend dialysis for isopropanol serum levels greater than 400 mg/dL. Coma itself is not an indication for dialysis but may necessitate mechanical ventilation. Peritoneal dialysis and hemodialysis have been successful, but hemodialysis is much more effective and is preferred. Because of isopropanol’s rapid absorption, patients who are hemodynamically stable without coma during the first 6 hours are at low risk for developing significant sequelae and generally do not require extracorporeal removal of isopropanol. The development of altered mental status within 2 hours is a clinical predictor of toxic blood isopropanol levels in children. Care is otherwise supportive and includes rewarming, administration of thiamine, evaluation for hypoglycemia, and monitoring for gastrointestinal bleeding.

ACKNOWLEDGMENT

The author would like to thank Deborah Mouzon for her assistance with the preparation of this chapter.

**KEY CONCEPTS**

- Small doses (single swallows) of methanol and ethylene glycol may cause toxicity.
- A latent period before the development of symptoms is characteristic for ethylene glycol and methanol toxicity, especially when ethanol has been co-ingested.
- A double-gap acidosis (anion gap and osmol gap) should suggest methanol or ethylene glycol toxicity.
- Toxic alcohol exposure cannot be ruled out by a “normal” osmol gap.
- Therapy should begin immediately based on clinical suspicion of exposure to ethylene glycol or methanol.

Acidosis should be corrected rapidly with bicarbonate, cofactors should be administered, and ADH should be blocked with ethanol or fomepizole.

- Because acidosis in the setting of exposure to either substance indicates toxic metabolite accumulation, immediate consultation for hemodialysis should be made, even before laboratory confirmation of toxic ethylene glycol or methanol levels.
- The presence of an osmol gap without acidosis is characteristic of isopropanol ingestion. Prolonged coma may be seen, and hypotension portends a poor prognosis.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
The term *hallucinogen* implies a single class of drugs, but these compounds have different chemical structures, mechanisms of action, and side effects. Most drugs usually do not produce actual hallucinations. Hallucinations are definitely not produced with marijuana, are possibly produced with phencyclidine (PCP), are occasionally produced with sympathomimetic amines, and are produced only with high doses of serotonergic agents. Almost any sympathomimetic compound can cause psychosis, paranoia, and other effects that some would classify as hallucinations but typically are misperceptions of real objects and more accurately termed *illusions*. This chapter describes serotonergic agents, sympathomimetic amines (entactogens), dissociative agents, and selected plants and fungi.

## SEROTONIN-LIKE AGENTS

### Perspective: Background and Epidemiology

Serotonin-like agents are a broad category of compounds that share chemical similarities to serotonin (5-hydroxytryptamine [5-HT]) or enhance serotonergic tone within the body. These agents include various lysergic acid derivatives and tryptamines. Serotonin-like agents produce changes in thought, mood, perception, and consciousness. Orientation to person, place, and time is preserved, but severe intoxication may cause confusion. Patients present to the emergency department because of acute panic reactions, massive ingestions, or accidental ingestions (e.g., children or adults who have ingested the drugs unknowingly). There is no addictive component in psychedelics and no euphoria-dysphoria cycle, as with cocaine, that would prompt a user to consume more. The rapid development of tolerance also limits the effect of repeated doses.

### LSD

Lysergic acid diethylamide (LSD), or “acid,” is the most potent psychoactive drug. Doses of 1 to 1.5 µg/kg produce psychedelic effects. The typical dose taken for an acid “trip” is approximately 25 to 100 µg. LSD is sold in tablets (microdots), liquid, powder, and gelatin squares (window pane), but the most common form of LSD is “blotter” acid. Sheets of blotting paper are sprayed with LSD, dried, and perforated into small squares. Graphics are stamped onto the blotting paper in designs that include cartoon characters (e.g., Felix the Cat) or geometric designs (Fig. 154-1). Each sheet is composed of hundreds of squares that are placed sublingually or eaten whole. Massive ingestions are rare.

In addition to synthetic LSD, several plants contain alkaloids similar in structure and action to LSD. These plants include Hawaiian baby woodrose (*Argyreia nervosa*), Hawaiian woodrose (*Merremia tuberosa*), morning glory (*Ipomoea violacea*), and ololuique (*Rivea corymbosa*). Intoxication may result after ingestion of the seeds or an extract.

### Tryptamines

Substances in the tryptamines category are naturally occurring and synthesized. For centuries, Central and South American Natives have used tryptamine-containing beverages, *ayahuasca*, in their religious ceremonies. Recently, this plant-derived drink, which contains dimethyltryptamine (DMT) and 5-methoxy-dimethyltryptamine (5-MeO-DMT), has gained popularity in Europe and North America. Designer tryptamines can be synthesized and possess the psychotropic effects of their naturally found compounds.

Psilocybin and psilocin are naturally occurring tryptamines found in some species of *Psilocybe* (Fig. 154-2), *Panaeolus*, and *Conocybe* mushrooms. Psilocybin is resistant to oxidation and remains active even when the mushrooms are dried or cooked. Street psilocybin sold as pills or capsules is usually substituted PCP or LSD. Misidentification and ingestion of other poisonous species is a danger of consuming mushrooms.

Naturally occurring tryptamines are found not only in plants and fungi but also in the parotid glands of the *Bufo* toad species. The venom of the Sonoran Desert or Colorado River toad (*Bufo alvarius*) contains the hallucinogenic substance 5-MeO-DMT, found in the drink ayahuasca. Smoking the dried venom results in psychoactive effects similar to those of 5-MeO-DMT.

In addition to the tryptamines that occur in nature, designer tryptamines have been synthesized and are orally active. Included in this group are α-methyltryptamine, diisopropyltryptamine, and diisopropyl-5-methoxytryptamine, which is also known on the streets as “foxy” or “foxy methoxy.” The effects of these synthetic derivatives are similar to those of naturally occurring tryptamines.
Principles of Disease: Pharmacology and Pathophysiology

Understanding of these drugs is incomplete, but evidence indicates that these drugs act on serotonergic neurons, particularly the 5-HT1A subtype class of serotonin receptors. One theory postulates that midbrain raphe cells send signals to higher centers via serotonin and that psychedelics change these transmissions, causing increased activity in the cerebral cortex and the limbic forebrain.

The onset of action of the psychoactive effects of LSD is usually within 30 minutes, with peak effects in 3 or 4 hours. The duration of effects may be approximately 12 hours. During the last half of the 12-hour effect, irritability, increased muscle tension (especially in the face), and paranoia can be present. Psilocybin effects begin within 30 minutes of ingestion, with the psychedelic phase lasting 30 minutes to 2 hours. The effects then wane, with resolution by 4 to 6 hours.

Clinical Features

In Western society, psychoactive agents are taken for internal mental exploration or more commonly for “recreation” at music concerts, at the beach, or in the woods. Changes include loss of boundaries between the user and the environment; the sensation that colors and sounds are distorted and intensified; and the perception that usual objects appear novel, fascinating, or awe-inspiring. This state differs from the confusional and dissociative state produced by PCP. Users are usually aware that they are under the influence of the drug. A sense of euphoria is typical, but it may alternate with intense dysphoric experiences that are accompanied by suffering (e.g., that of dying or being born).

Acute panic reaction is the most common adverse reaction to psychedelics. Paralytic delusions and fear of impending death may be present. Behavior is either agitated or, occasionally, withdrawn. Symptomimetic effects include dilated, reactive pupils and moderate increases in blood pressure, heart rate, and, rarely, temperature. Mydriasis seems to parallel the intensity of the trip. In contrast to PCP, nystagmus, ataxia, muscle rigidity, and increased secretions are not present.

The individual’s altered perceptions may result in lack of awareness of dangers in the environment, resulting in injury. Psychosis after LSD trips is reported, and schizophrenia (overt and borderline) may worsen. Transient depression sometimes occurs after LSD use. Flashbacks, or post-hallucinogen perceptual disorder, are transient episodes of altered consciousness that occur months or years after an LSD trip. However, LSD use and these episodes have not been shown convincingly to have a cause-and-effect relationship.

Massive ingestions may result in a person becoming comatose and unresponsive to pain. The person may also be hyperactive with marked auditory and visual hallucinations. Fixed and dilated pupils, diaphoresis, vomiting, bleeding complications, and seizures may result. Euphoria and a distortion of reality usually occur after ingesting 1 to 5 *Panaeolus cubensis* mushrooms. Transient nausea is uncommon, and in contrast to peyote, vomiting is unusual. Larger doses (5–20 *P. cubensis* mushrooms) produce visual hallucinations. Few adverse reactions occur, and the incidence of “bad trips” or panic reactions is lower than with LSD. There are reports of seizures, coma, and hyperthermia after psilocybin use.

Diagnostic Strategies

Because most patients are either in a panic or brought in by a worried companion, the drug is usually known. Although mass spectrometry can identify psychedelics in serum, urine, or gastric contents, it is not available in the clinical setting, so diagnosis and treatment are based on clinical grounds. Even when tests are available, however, the results are delayed and only useful to confirm or document the event. Interference with routinely available drugs of abuse does not typically occur.

Differential Considerations

Other drugs or mixed ingestion are a possible source of the patient’s symptoms, especially with coma or marked physiologic changes. PCP, cocaine, and amphetamines must be considered because their effects may require specific treatment. Schizophrenia may appear similar to psychedelic ingestion, but the time course is much longer.

Management

The basic principle of out-of-hospital care is reassurance and supportive care. If the patient is a danger to him- or herself or others, the patient may need to be restrained temporarily to...
permit sedation or be sedated without need for restraint. There is no specific antagonist to the effects of serotonergic agents. An important therapeutic modality is empathic reassurance in a calm, quiet environment. The effects last for hours, but when they wear off, the patient feels normal again.

Benzodiazepines, such as lorazepam (1 or 2 mg intravenously, then titrated to effect), can be given safely to decrease agitation. Phenothiazines should be avoided in case the symptoms are actually caused by an anticholinergic drug and not a psychedelic. Butyrophenones, such as haloperidol or droperidol, may be given by intramuscular or intravenous injection in doses titrated to clinical response if the patient is violent and must be sedated. Monitoring for QT prolongation is recommended, if possible, when a butyrophenone is used.

Disposition

Patients with anxiety or panic reactions can be talked down and sent home with responsible family or friends. Patients who persist with confused or paranoid behavior should be admitted. If the diagnosis is in question, the patient should be observed for several hours for significant changes in the condition. Follow-up evaluation should be recommended with a psychiatrist, primary care physician, or drug counseling facility. Patients with massive ingestions or having incurred injuries or medical complications (rhabdomyolysis) may need admission to a monitored setting for serial reassessments.

ENTACTOGENS

Perspective: Background and Epidemiology

Hallucinogenic stimulants, also called entactogens, are structural analogues of amphetamine, mescaline, and N-substituted piperazines. These agents share effects in varying degrees of true stimulants and the serotonin-like hallucinogens.

Designer Amphetamines

New designer amphetamines were originally developed chemically to circumvent the law before the advent of the prospective standard for the Controlled Substances Act (CSA) and appear in drug communities each year. These agents include 3,4-methylenedioxymethamphetamine (MDMA, Ecstasy, XTC, or Adam), 3,4-methylenedioxyamphetamine (MDA), 3,4-methylenedioxymethamphetamine (Eve), paramethoxyamphetamine (PMA or death), and 4-methyl-2,5-dimethoxyamphetamine (serenity, tranquility, and peace [STP]).

MDMA is the best known of these agents. It was first synthesized in 1914 as an appetite suppressant. Recreational and psychotherapeutic use began in the late 1970s and has increased in recent years, especially on college campuses, where 39% of students have tried this drug. Australian surveys report up to 20% of those age 20 to 29 years have used MDMA. MDMA and MDA have been called “love drugs” because of claims from users that sexual pleasure and feelings are heightened, but the sympathomimetic effects of these drugs may produce erectile dysfunction. MDMA can produce euphoria, increase emotional awareness, and has been reported to improve interpersonal communications. The psychedelic and stimulant effects of MDMA are preferred over MDA by most users. Overt hallucinations of the type experienced with LSD are rare; however, sensory enhancement and distortion and illusions can occur. Because of these effects, Nichols suggested that these drugs represent a new drug class called entactogens (i.e., enabling the user to “touch within”). This concept is based on clinical effects in humans and on drug discrimination studies in laboratory animals. MDMA was classified as a Schedule I drug by the Drug Enforcement Agency (DEA) in 1985.

Entactogens are predominantly used in three main settings: as “psychotherapeutic adjuncts,” recreationally in small groups or by couples, and at dance clubs or “rave” parties. Some psychiatrists or psychotherapists have used entactogens as pharmacologic adjuncts to increase emotional awareness, interpersonal closeness, and introspection during psychotherapy. MDMA is still being studied in low doses as an adjunct to therapy for anxiety. Rave parties are all-night dances held in warehouses or dance halls. Nonstop dancing occurs to loud, repetitive, electronically synthesized “techno” music, and a variety of hallucinogens and amphetamine derivatives are consumed, especially MDMA. “Herbal ecstasy,” known as ma-huang or ephedra, is sometimes substituted for MDMA at these gatherings when MDMA is scarce. Although this herb contains ephedrine, its effects are not as psychedelic as MDMA. Ecstasy tablets may also contain other chemicals, such as amphetamine, methamphetamine, caffeine, and ketamine. MDMA is widely available and is sold in clubs, on the street, and at raves (usually 30–150 mg/pill), with a typical dose of 1 or 2 mg/kg.

The continuous muscular activity required during these parties may combine with MDMA and other psychostimulants to produce rhabdomyolysis and hyperthermia. Nine deaths in Canada associated with PMA were originally reported in 1974, but clusters of multiple deaths in association with PMA exposure have occurred in Europe and Australia. Because of the popularity of MDMA, PMA is reportedly being sold under the guise of MDMA. Signs and symptoms of adrenergic excess occur before death, but whether PMA is more toxic in equipotent dosages than other amphetamines is not known.

Mescaline

Mescaline is usually consumed in the form of peyote “buttons,” which are derived from the small blue-green cacti Lophophora williamsii and Lophophora diffusa (Fig. 154-3). The cacti grow in the deserts of the southwestern United States and Mexico. Peyote buttons are the round fleshy tops, which are removed and dried. Mescaline is the active hallucinogenic alkaloid found in the buttons of the cactus.

Peyote has been used in religious ceremonies for 8000 years. Mescaline is also contained in the San Pedro cactus (Trichocereus...

**Principles of Disease: Pathophysiology**

The psychoactive effects of MDMA and other entactogens are thought to result from alterations in catecholamine neurotransmission at postsynaptic and presynaptic sites, particularly affecting 5-HT. These agents cause a release of serotonin, dopamine, and norepinephrine from nerve terminals, as well as inhibit catecholamine reuptake. Release of epinephrine and norepinephrine may produce the cardiovascular effects. MDMA and possibly other entactogens are serotoninergic neurotoxins.  

When MDMA is administered to nonhuman primates and laboratory animals, serotonin is released initially from serotoninergic neurons followed by degradation of 5-HT projections. Magnetic resonance imaging shows significant neurodegeneration. These effects may persist for weeks or longer after a single dose. The significance of this neurotoxic effect for humans at the dosages taken is unknown.

Psychostimulant-associated hyperthermia is well described in humans. Animal models exposed to entactogens develop hyperthermia in the absence of physical exertion but are less capable of regulating core body temperature in response to environmental hyperthermia. In addition, increasing body temperature in the presence of MDMA or other entactogens seems to enhance serotoninergic neurotoxicity.

**Clinical Features**

MDMA effects last 3 to 5 hours. Blood pressure increases during the first hour and gradually returns to baseline within 6 hours. CNS effects of MDMA may persist for 6 to 12 hours. Larger dosages or greater frequency dosing of MDMA may lead to more frequent unpleasant side effects, such as agitation or confusion. Recreational users rarely report dysphoria.

Clinical effects expected from the entactogens would be similar to clinical effects of other amphetamine derivatives (see Chapter 152). Death after ingestion is most often linked to hyperthermia. Deaths at rave parties typically involve seizures and hyperthermia at recreational dosages. Dehydration and high ambient temperatures during rave parties may be contributing factors. The mechanism behind psychostimulant-induced hyperthermia is unclear but likely combines CNS factors and seizure activity with drug effects. Rhabdomyolysis can occur from a combination of direct toxic effects of the agent, extreme physical activity, and hyperthermia. Preexisting cardiac disease may contribute to sudden death, presumably from dysrhythmias. MDMA may precipitate a hypertensive crisis in patients taking monoamine oxidase inhibitors, and it may precipitate serotonin syndrome when combined with other serotoninergic agents. MDMA and its analogues also have contributed to fatal overdoses.

**Diagnostic Strategies**

Urine screening with immunoassay techniques can detect entactogens. Small dosages may not be detected, but larger doses test positive for amphetamine-methamphetamine. Designer amphetamines, including MDMA, and their metabolites may be detectable with thin-layer chromatography methods.

**Differential Considerations**

All sympathomimetic compounds, including cocaine, amphetamine derivatives, PCP, and LSD, can present with violent and psychotic behavior, convulsion, coma, and any combination of sympathomimetic signs and symptoms. Many of these reactions may not be from overdose but, rather, from idio-pathic and unpredictable toxic reactions. Initial management is consistent for each of these compounds.

**Management**

Patients with panic reactions or violent psychotic episodes should be placed in a quiet environment and reassured. Diazepam, 2 to 10 mg, or lorazepam, 1 or 2 mg, can be administered orally to cooperative patients. Repeat doses of diazepam, 5 to 10 mg (intravenously [IV]), or lorazepam, 2 to 4 mg (intramuscularly [IM] or IV), can be used in violent subjects. Butyro-
ph en o mes, such as haloperidol and droperidol, may also be used. Hypertension and tachycardia should be treated with liberal sedation. If necessary, alpha-adrenergic antagonists in combination with vasodilators may be used. Dysrhythmias should be treated in the usual manner.

Because hyperthermia is a common complication, a core temperature should be obtained. If the patient’s temperature is greater than 40° C to 42° C, multiple organ damage often results in fatalities. Active cooling measures should be immediate and aggressive because the outcome strongly correlates with the presenting temperature and length of time the patient has been hyperthermic. Rapid sequence intubation, paralysis with a nondepolarizing neuromuscular blocker, intravenous fluid resuscitation, and water misting and fans should be used. Rhabdomyolysis, myoglobinuric renal failure, hepatic damage, and disseminated intravascular coagulopathy may accompany hyperthermia.\textsuperscript{43,44} Treatment of hyponatremia should proceed in the usual manner. Aggressive pharmacologic management of nausea and vomiting may be necessary with peyote and nutmeg ingestions.

### Disposition

Most patients with a toxic reaction or overdose to an entactogen who are not hyperthermic or do not have abnormal cardiac rhythms resolve their symptoms in several hours. Psychiatric assessment may be necessary if psychotic or abnormal thoughts or actions persist longer than this time period. Although urine screening will not guide treatment decisions, it may aid the psychiatrist in counseling.

Patients with ongoing or severe toxicity to these agents require admission to the hospital. Seizures, cardiac dysrhythmias, myoglobinuric renal failure, hepatic damage, and heat-related problems should be monitored in an intensive care unit or step-down unit. Direct sympathomimetic toxicity resolves over 24 hours, but sequelae may require prolonged hospitalization.

### DISSOCIATIVE AGENTS

#### Perspective: Background and Epidemiology

PCP and ketamine are the two main agents included in the class of dissociative agents. They are similar in chemical structure and pharmacologic effect. PCP and ketamine are general anesthetics causing dissociation of the patient from the environment. They have analgesic and amnestic activity but do not cause respiratory or cardiovascular depression.

#### Phencyclidine

PCP was initially marketed for use as a general anesthetic; however, severe emergent reactions rapidly led to its recall. In the 1960s, PCP was sold as the “PeaCe Pill,” which was consumed orally, but the effects were often unpredictable and unpleasant. In the mid-1970s, PCP was the most common cause of recreational drug-related emergencies. Its popularity decreased because of unpredictable effects, a long clinical course, dysphoria, and association with violence. In 1978, PCP was classified as a Schedule I drug.

#### Ketamine

The similarities between PCP and ketamine virtually guaranteed the eventual abuse of ketamine. Spurred by the rave party fad and the Internet (going by the names of “vitamin K” or “special K”), ketamine is one of the most rapidly increasing drugs of abuse in some areas of the United States, especially near the Mexican border. Preparations available on the street are often adulterated with various stimulants. The most common use of street ketamine is insufflation, but subcutaneous and intramuscular injection and even rectal infusion are done to achieve a level of intoxication or “high” known as the “K hole.”

#### Dextromethorphan

Dextromethorphan is not truly a dissociative agent but does share a similarity in structure to PCP and other opioid compounds and its binding to the PCP site of the \( N \)-methyl-D-aspartate (NMDA) receptor. The abuse potential became reality in the 1990s with high school–age individuals (13–17 years) abusing dextromethorphan.\textsuperscript{45,46} The Internet has also played a major role in popularizing the misuse of this agent. Referred to as “DXM,” “Robo,” and “skittles,” dextromethorphan predominates on many Internet websites devoted to rave parties, drug use, and experimentation.

#### Principles of Disease: Pharmacology and Pathophysiology

Despite being simple molecules, the pharmacology of PCP and ketamine is complex, with agonist and antagonist actions at numerous sites, including the NMDA receptor, dopamine/norepinephrine-serotonin reuptake pump, sigma-opioid receptor, and cholinergic receptors.\textsuperscript{47} PCP is well absorbed from any oral, nasal, or rectal mucous membrane and can be insufflated or smoked. It can be injected intramuscularly, subcutaneously, or intravenously. Ingested PCP is well absorbed in the small bowel, with onset between 15 and 60 minutes. When smoked, PCP produces symptoms within 5 minutes, with peak activity in 15 minutes.\textsuperscript{48} Intoxication with PCP usually ranges from 8 to 16 hours, but it can be longer in chronic users. Although enterohepatic recirculation has been proposed, more likely causes are either gastrointestinal concretion or delayed release from lipid stores.\textsuperscript{49}

Ketamine is only approximately one tenth as potent as PCP.\textsuperscript{50} With ketamine, the intensity of intoxication is less pronounced, although in higher dosages the effects may parallel those of PCP. Duration of action of ketamine is typically shorter, with symptoms lasting approximately 1 hour after insufflation but may be prolonged 4 to 8 hours after oral dose. PCP and ketamine are highly lipid-soluble agents that undergo extensive metabolism in the liver and are excreted eventually in the urine.

Dextromethorphan is the dextrorotatory isomer of the synthetic opioid levorphanol. Although typically classified as an opioid, its pharmacology is complex. It inhibits the uptake of serotonin and blocks the NMDA receptor at the PCP binding site.\textsuperscript{50} At high dosages, dextromethorphan is an agonist at the sigma opiate receptor and naloxone has been reported to reverse intoxication.\textsuperscript{51} Drug interactions with selective serotonin reuptake inhibitors and monoamine oxidase inhibitors are also reported.\textsuperscript{52}

#### Clinical Features

Patients with PCP intoxication have a wide spectrum of findings, with autonomic signs and symptoms often similar to other sympathomimetic agents. Behavior may be bizarre, lethargic, agitated, confused, or violent. A blank or catatonic stare is common. Vertical, horizontal, and rotary nystagmus is often present. Moderate hypertension and tachycardia may be present. Pupils usually are midsized and reactive, although
there may be miosis or mydriasis. Bizarre posturing, grimacing, and writhing may be seen.53

Other variable findings include ataxia, muscle rigidity, increased deep tendon reflexes, increased secretions, bronchospsm, hyperthermia, and seizures. The percentage of violent patients ranges from 10 to 40% for PCP, and controlling these patients may be the most challenging problem in the emergency department. “Superhuman” strength is possible because of the dissociative action of PCP. Patients have broken police handcuffs, fracturing bones in doing so, and have performed other destructive actions not normally possible. Although mild hypertension in PCP intoxication is common, hypertension requiring antihypertensive treatment is rare. Severe hypertension with PCP overdose has caused intracerebral hemorrhage but not as commonly as with cocaine or amphetamine.54

Hyperthermia can range from mild to life-threatening. Core temperatures of PCP victims can exceed 40°C and often go undetected for prolonged periods in the emergency department. Severe hyperthermia with temperatures greater than 42°C resembles heatstroke and is often associated with multiple organ damage.55 Particularly susceptible organs are the kidneys, liver, heart, and brain. High-output congestive heart failure has been reported. The presumed mechanism is muscle damage from seizures, extreme muscular activity such as struggling against restraints, or prolonged immobility. Rhabdomyolysis and acute myoglobinuric renal failure are the most common serious medical complications. Renal function returns after several weeks in most cases. Among the most lethal complications of PCP are respiratory depression, apnea, and cardiac arrest.55

Although dextromethorphan has activity at opioid receptors, the typical triad of opioid intoxication (miosis, respiratory depression, and mental status depression) generally is not encountered.56 Similar to meperidine, dextromethorphan intoxication may result in mydriasis through paralysis of the ciliary body.57 More typical clinical findings are lethargy, agitation, blurred speech, ataxia, diaphoresis, hypertension, and nystagmus.58 With higher doses, nausea and vomiting are common, and intoxication resembles that of LSD with euphoria and hallucinations. Dystonic reaction has been reported in a child after therapeutic administration.59

Diagnostic Strategies
Most hospital laboratories use radioimmunoassays that can detect urinary PCP with a detection limit of 5 ng/mL. Urine may be positive for 2 to 4 days after PCP use, but it can be positive for more than 1 week after chronic exposure. Serum screening for PCP is of little clinical benefit because levels correlate poorly with symptoms. Several substances may cross-react with urine screens for PCP, including dextromethorphan, due to their structural similarities. Chlorpromazine, methadone, ketamine, and diphenhydramine may also cross-react with some assays.59 Because dextromethorphan is typically formulated as a hydrobromide salt, chronic use may result in spurous hyperchloremia with a low or negative anion gap due to interference of chloride analysis by the bromide ion in the autoanalyzer.60

Differential Considerations
PCP, ketamine, and dextromethorphan intoxications can mimic such diverse entities as head trauma, meningitis, catatonia, or heatstroke. Sympathetically mediated vital sign changes can be found in numerous other agents, including cocaine, amphetamine, and LSD. Antimuscarinic compounds, such as diphenhydramine, benztrapine, and tricyclic antidepressants, can also simulate the tachycardia and altered mental status found with PCP or ketamine. Salicylate poisoning, thyrotoxicosis, and sepsis should be considered. Meningitis, intracerebral hemorrhage, and viral encephalitis can present with altered mental status of unclear etiology. Even with a PCP positive urine screen, the diagnosis is not certain unless a definite history of recent PCP, ketamine, or dextromethorphan use is obtained and other conditions have been eliminated.

Management
Out of Hospital
Life-threatening complications, such as apnea or seizures, should be stabilized before transport. The threat of violence to nonhospital care providers from patients with PCP poisoning makes it dangerous for only two or three nonhospital care providers to restrain these patients until additional help arrives. Oxygen and glucose testing should be deferred until the patient is controlled. Violent patients under the influence of PCP may have traumatic injuries.

Emergency Department
Patients with PCP toxicity can have unpredictable, violent behavior or sudden complications, such as cardiac arrest or seizures. Violent behavior, although possible, is less common with ketamine. Most patients with minor intoxication are alert, oriented, and neurologically normal after 4 to 6 hours.54 All patients with signs of trauma or struggle should be evaluated for injuries. Reliable assessments of these individuals are difficult, and sedation and restraint are often necessary before diagnostic tests or examinations can be performed.

Chemical sedation or restraint is preferred to physical restraint in cases of PCP or ketamine intoxication, although temporary physical restraint may be necessary to ensure patient safety, establish intravenous access, and administer IV benzodiazepines. Assessment of mental status may not be as reliable after chemical sedation, but the benefits of protecting the staff and patient far outweigh the disadvantages. Haloperidol, 5 to 20 mg IM or IV, or droperidol, 2.5 to 10 mg IM or IV (noting the Food and Drug Administration black box warning), is usually an effective means of chemical restraint in these patients. These agents may antagonize CNS receptor sites that are responsible for much of the violent behavior in these individuals. Benzodiazepines such as lorazepam, 2 to 4 mg IV or IM, or diazepam, 5 to 10 mg IV, may be used in aggressive dosages to calm patients with all types of sympathomimetic poisonings. A well-coordinated team may be needed to apply hard restraints simultaneously to all four extremities and the body.

Comatose patients or patients with a questionable airway should be intubated to ensure adequate ventilation. Although PCP intoxication can cause mild hypotension, profound hypotension is probably the result of trauma or a mixed-drug ingestion, and the patient should be resuscitated with fluids. Seizures should be treated with IV benzodiazepines. Phenobarbital, 20 mg/kg IV, may be used for refractory seizures. Tachycardia does not require additional treatment except for sedation.

Hyperthermia (temperature >40°C) is common in severe cases of PCP poisoning. All patients with significant symptoms, psychosis, or history of violent behavior should have rectal temperatures measured. Individuals with elevated temperatures should be treated aggressively with active cooling measures.
Renal status and creatine kinase (CK) should be monitored to detect rhabdomyolysis and myoglobinuric renal failure. Urinary acidification had been used in the past to trap PCP in urine and aid elimination, but its use has been abandoned because of the insignificant renal clearance of the drug (10%) and the potential adverse impact of acid urine on myoglobin in renal tubules that is often present after PCP intoxication. Activated charcoal is of no value in acute intoxication, but a standard oral dose of 50 g may be considered when body packing is suspected. If patients have never been hyperthermic and have no signs of trauma, laboratory or other diagnostic tests are not needed.

Dextromethorphan poisoning can be managed with supportive care and measures to prevent injury to the patient. Sedation with a benzodiazepine may be used for agitation. The patient should improve over 4 to 6 hours. Many dextromethorphan cough and cold preparations also contain acetaminophen, so acetaminophen levels should be measured.

**Disposition**

For nonviolent patients with PCP intoxication, a quiet holding room is ideal for 4 to 6 hours of observation. Patients with violent behavior or obtundation often require admission to the hospital, where close observation and treatment of potential life-threatening complications can be accomplished. Serial chemistry evaluations, including serum creatinine and CK, should be monitored. Most of these patients can be medically cleared the next day.

---

**MARIJUANA AND MISCELLANEOUS PLANTS AND FUNGI**

**Marijuana**

**Perspective: Background and Epidemiology**

Marijuana is the most common illegal drug in the United States. It has been used medicinally since ancient times for conditions such as colic and asthma but has been illegal since 1937. The use of marijuana peaked in the late 1970s, with 20 million smokers, but declined during the 1980s. Today, there are more than 12 million users in the United States and more than 300 million regular users estimated worldwide.

*Cannabis sativa* and *Cannabis indica* plants are some of the earliest plants grown by humans. Bioactive substances derived from these plants are collectively called cannabinoids. The seedless flowering tops of the female plant are referred to as sinsemilla and are the commonly grown form of marijuana in the United States. The resin from the flowers is made into hashish. Marijuana is smoked or eaten blended into foods, such as brownies.

**Principles of Disease: Pharmacology and Pathophysiology**

Δ9-Tetrahydrocannabinol (THC) is the main active agent of more than 61 cannabinol compounds and approximately 300 other substances present in the cannabis plant. Marijuana smoke also contains carbon monoxide, cyanide, acetone, and phenol, but not nicotine. The most efficient route of THC delivery is by inhalation. Fifty percent of smoked THC is absorbed compared with 6% by ingestion. Experienced users may be able to absorb higher doses with breath-holding techniques. Peak blood levels occur within 8 minutes of inhalation, with rapid distribution into tissues, especially tissues with high lipid content. The duration of perceived effects is usually 2 to 4 hours when smoked and 6 to 12 hours when ingested.

**Clinical Features: Acute Signs and Symptoms**

Smoking leads to rapid and more predictable signs and symptoms. Ingestion can cause delayed and sometimes unpredictable effects. The most common effects from smoking marijuana include alteration of mood and usually relaxation and euphoria. The only reliable physiologic effects are a mild increase in heart rate and conjunctival injection. Pupillary changes usually do not occur. Other acute peripheral changes include urinary retention, decreased testosterone levels, and decreased intraocular pressure. Short-term memory is impaired, and the ability to perform complex tasks may be adversely affected. Many users report excessive appetite after marijuana use. The most common adverse reaction is panic, paranoia, or acute psychosis, particularly with novice users or individuals with preexisting psychiatric disease. These episodes are usually transient and reality testing remains intact. Even when “high-potency” marijuana is smoked continuously for hours, adverse effects are rarely seen. Users become more sedated as they continue to smoke but do not become unarousable. No deaths have been solely attributed to marijuana. Pediatric exposures to marijuana may lead to hypothermia, ataxia, nystagmus, tremor, tachycardia, injected conjunctiva, and labile affect. Oral ingestion of potent marijuana in children can produce rapid onset of drowsiness, hypotonia, and lethargy, which can lead to coma and airway obstruction.

**Diagnostic Strategies**

Marijuana screening is not helpful in the emergency department. Urinary metabolites of THC are detectable within 1 hour after smoking marijuana, but a positive urine test does not correlate with acute intoxication. A single marijuana cigarette can be detected for 72 hours when a 100 ng/mL cutoff level is used, and positive urine levels may persist for 3 months after chronic marijuana use. Inadvertent or passive exposure to marijuana can produce positive urine testing. False-positive urine screen results may be produced by efavirenz, ibuprofen, and naproxen.

**Differential Considerations**

The presentation that most closely resembles marijuana intoxication is acute psychosis. Some individuals with underlying and preexisting psychiatric disorders may progress to overt psychosis after heavy or first-time marijuana use. Because marijuana is so readily available, it is commonly a co intoxicant used with ethanol and other psychotropic agents. Rarely, marijuana can be adulterated with other substances such as lead.

**Management and Disposition**

Care of patients intoxicated from marijuana consists of prevention of injury and reassurance of those who have panic reactions. An extremely agitated patient can be sedated with oral or parenteral benzodiazepines. Children who are significantly symptomatic may require admission.

**Salvia**

*Salvia divinorum* is a perennial herb cultivated well outdoors in mild climates and is a member of the mint (Lamiaceae) family. Common names for *S. divinorum* include “diviner’s
sage,” “mystic sage,” “magic mint,” “sage of the seers,” “Sally-D,” and “ska Maria Pastora.” Although the plant has been used for divination and shamanism by the Mazatec Indians of Oaxaca, Mexico, S. divinorum has become popular in the past decade for recreational purposes because of its recognized hallucinogenic properties and continues to be sold legally by online vendors and “smoke” or “head” shops. In 2004, the DEA listed S. divinorum as a “drug of concern,” but to date, it remains unscheduled under the CSA. Several states, however, have instituted or are considering legislation making possession, cultivation, and use of S. divinorum or its extracts illegal. Internationally, regulatory controls have been implemented in Australia and a number of European countries.

The active ingredient in S. divinorum is salvinorin A (a.k.a. divinorin A), a neoclerodane diterpene with selective agonist activity for kappa-opioid receptors (KORs), but it does not bind to delta- or mu-opioid receptors. Salvinorin A is the first naturally occurring non-nitrogenous KOR agonist with psychotropic properties and is the most potent plant hallucinogen discovered to date. The threshold dose of salvinorin A producing hallucinations is comparable to synthetic LSD and 4-bromo-2,5-dimethoxyphenylisopropylamine. Stimulation of KOR in the brain and spinal cord produces psychomimetic and analgesic effects, respectively. However, salvinorin A is distinct from more traditional hallucinogens because it does not bind to the 5-HT2A serotonin receptors as is the case with LSD.

Salvia is usually chewed and either spit out or swallowed, and it seems to be absorbed better from the oral mucosa than from the rest of the gastrointestinal tract. Effects produced as a result of oral mucosal absorption may persist for 1 hour. Dried leaves also can be smoked. Inhalation of smoke can produce symptoms within 1 minute that subside over 20 to 30 minutes. Sensations experienced are variable but include distortions of color and vision as well as auditory, visual, gustatory, and olfactory synesthesias that are confusions of the senses, such as seeing sounds, hearing touches, or smelling visions. Salvia divinorum is often used in conjunction with other agents, such as marijuana and MDMA.

Salvinorin A is not detected and is not known to cause interference with routine drug screens used in the clinical setting. Management of intoxication from S. divinorum is mainly supportive with emphasis on injury prevention. Use of naloxone, a non-specific opioid receptor antagonist, may theoretically be helpful in reversal of psychotropic manifestations.

Kratom

Mitragyna speciosa Korth, or Kratom, is a tree indigenous to Thailand but is also found in tropical and subtropical regions of Asia and Africa. Its extracts have been used in Thailand and Malaysia for their euphoric effect as a substitute for opium or to moderate opium use by addicts. The popularity of Kratom has grown due to reports of its successful use to attenuate symptoms of opioid withdrawal. Because Kratom remains easily obtainable from Internet sources, individuals are able to self-administer the perceived remedy, obviating the need for physician supervision. The safety of such practice is unknown.

Although Kratom extract contains more than 25 alkaloids, mitragynine is the most abundantly found in the plant. Mitragynine is an indole alkaloid with structural analogy to yohimbine and has agonist activity at mu- and delta-opioid receptors producing euphoric, analgesic, and respiratory depressant effects. Despite its structural similarity to yohim-
structural analogues of endogenous neurotransmitters glutamic acid (excitatory) and GABA (inhibitory) and thought to act at these respective receptor sites. The excitatory effects characterized by elation, giddiness, hyperactivity, muscle tremors, and distortion of space-time begin approximately 20 to 60 minutes after ingestion and are likely mediated by ibotenic acid. Following is a phase of tiredness and deep “sleep” in which it may be difficult to arouse the patient. During this phase, vivid hallucinations and manic excitement may alternate with periods of deep sleep. The duration of effect is 6 to 12 hours. Management of the excitatory phase is similar to that of other hallucinogens previously described in this chapter. Prolonged sleep with A. muscaria ingestion requires only observation or supportive care. Tonic-clonic seizures are reported, but deaths are rare.

Because elements of isoxazole poisoning resemble manifestations seen with anticholinergic toxicity, these mushrooms have also been referred to as “anticholinergic” mushrooms; however, belladonna alkaloids are not present. Paradoxically, there has been a high incidence of mistreatment of A. muscaria ingestion with atropine because the name implies that it contains muscarine, a cholinergic toxin. However, the amount of muscarine is very small (<0.0002% in fresh specimens). Many textbooks recommend the use of atropine, but atropine may exacerbate the anticholinergic effects associated with isoxazole mushrooms. It is important to differentiate isoxazole-containing Amanita mushrooms from the deadly hepatotoxic cyclopeptide-containing Amanita mushrooms, of which A. phalloides is a member.

Figure 154-4. Amanita muscaria mushroom. (Photo by Mark Shubert. Copyright © 2004 Erowid.org. Accessed at http://www.erowid.org.)

renal failure secondary to rhabdomyolysis. Treatment is supportive.

Isoxazole Mushrooms

Isoxazole-containing mushrooms include Amanita muscaria, Amanita pantherina, Amanita gemmata, and Amanita cothurnata. Amanita muscaria has a red or yellow cap with white warty structures on its surface and grows in forests of aspen, birch, fir, or pine trees (Fig. 154-4). It has been used by Siberians for centuries and is often described in folklore and fairy tales. Pharmacological evidence indicates that several modern religions began as A. muscaria cults.

The active ingredients are the isoxazole derivatives ibotenic acid and its decarboxylation product, muscimol, which are

**KEY CONCEPTS**

- Hallucinogens include many types of drugs with different associated effects.
- Diagnosis and management are based primarily on the history and physical examination.
- Reassurance and supportive care suffice for most patients.
- Aggressive sedation is necessary in agitated and violent patients.

_The references for this chapter can be found online by accessing the accompanying Expert Consult website._
Iron, which is essential to the function of hemoglobin, myoglobin, many cytochromes, and many catalytic enzymes, can be extremely toxic when levels are elevated following an overdose or from accumulation in disease states. The acute ingestion of iron is especially hazardous to children. Ingestions of pediatric multivitamin formulations are the most common iron exposures. These occur in children younger than age 6 years and are minimally toxic. Life-threatening toxicity is associated with ingestion of potent adult preparations, such as prenatal vitamins. Serious iron ingestions in adults are usually associated with suicide attempts.

Principles of Disease
Pharmacology
Under normal conditions, approximately 10% of ingested iron is absorbed from the intestine and bound to transferrin, using only 15 to 35% of the iron-binding capacity of transferrin. Normal serum iron levels range from 50 to 150 µg/dL. The total iron-binding capacity (TIBC), a crude measure of the ability of serum proteins—including transferrin—to bind iron, ranges from 300 to 400 µg/dL. It is higher than the serum iron level due to a low degree of saturation. When iron levels rise following a significant iron overdose, transferrin becomes saturated so that excess iron circulates as free iron in the serum. This unbound iron is directly toxic to target organs.

When assessing the severity of an iron exposure, it is important to refer to the amount of elemental iron ingested because the toxicity of an iron compound depends on the amount of elemental iron it contains. Different formulations of iron salts contain different percentages of elemental iron. The total amount of elemental iron ingested can be approximated by multiplying the estimated number of tablets by the fraction of elemental iron contained in the tablet. Ingestions of less than 20 mg/kg of elemental iron usually cause no symptoms. Ingestion of 20 to 60 mg/kg results in mild to moderate symptoms, and ingestion of more than 60 mg/kg may lead to severe morbidity. Although the dose of elemental iron associated with 50% mortality (LD₅₀) is reported to be 200 to 250 mg/kg, doses as small as 130 mg of elemental iron have been lethal in children. A newer uncharged form of iron (carbonyl iron) is very slowly absorbed. There are no reported cases of serious toxicity or death from the ingestion of this compound.

Pathophysiology
Iron has two distinct toxic effects: (1) it causes direct caustic injury to the gastrointestinal mucosa, and (2) it impairs cellular metabolism, primarily of the heart, liver, and central nervous system (CNS). The caustic effects of iron on the gut cause the initial symptoms of vomiting, diarrhea, and abdominal pain. Hemorrhagic necrosis of gastric or intestinal mucosa can lead to bleeding, perforation, and peritonitis.

Unbound (free) iron moves into cells and localizes near the mitochondrial cristae, resulting in uncoupling of oxidative phosphorylation and impairment of adenosine triphosphate synthesis. Cell membranes are injured by free radical-mediated lipid peroxidation. Iron increases capillary permeability and induces both arteriolar and venodilation. Myocardial toxicity decreases cardiac output. Hydration of the iron molecule creates an excess of unbuffered protons, worsening metabolic acidosis. This multitude of effects, combined with severe gastrointestinal fluid losses, can lead to the development of shock, cardiovascular collapse, and death.

Clinical Features
The clinical effects of acute iron poisoning are described by five stages. Phase I reflects the corrosive effects of iron on the gut. Vomiting occurs within 80 minutes of ingestion in more than 90% of symptomatic cases. Diarrhea, which can be bloody, follows. Phase II represents an apparent (but not complete) recovery that lasts less than 24 hours but can extend up to 2 days. Most patients recover after this point. Phase III is characterized by the recurrence of gastrointestinal symptoms, severe lethargy or coma, anion gap metabolic acidosis, leukocytosis, coagulopathy, renal failure, and cardiovascular collapse. Serum iron levels may have fallen to normal during this phase due to distribution into the tissues. Metabolic derangements due to iron poisoning include hypoglycemia, leukocytosis, and severe lactic acidosis from hypoperfusion and interference with cellular respiration. Early coagulation defects are probably related to direct effects of iron on vitamin K–dependent clotting factors. Later coagulation defects are due to hepatic failure. Hypoglycemia and elevations of bilirubin, aspartate, and alanine aminotransferases are other markers of hepatotoxicity. Phase IV, characterized by fulminant hepatic failure, occurs 2 to 5 days after ingestion. This is relatively rare, appears to be dose related, and is usually fatal. Phase V represents the consequences of healing the injured...

Gastrointestinal mucosa. It is characterized by pyloric or proximal bowel straining, which is sometimes associated with obstruction.16,10

Diagnostic Strategies

The presence of gastrointestinal symptoms suggests a potentially serious ingestion, whereas their absence is reassuring. A serum iron level measured at its peak, 3 to 5 hours after ingestion, is the most useful laboratory test to evaluate the potential severity of an iron overdose. Sustained-release or enteric-coated preparations may have erratic absorption, so a second level 6 to 8 hours after ingestion should also be checked. Peak serum iron levels of less than 350 µg/dL are generally associated with minimal toxicity, 350 to 500 µg/dL with moderate toxicity, and greater than 500 µg/dL with potentially severe toxicity (Table 155-2).4 Because iron is rapidly cleared from the serum and deposited in the liver, iron levels may be deceptively low if measured late, even after a substantial ingestion.

TIBC has been used in the past as an indicator of free iron. However, TIBC is a crude test, and cases of serious toxicity have been reported even when TIBC exceeds the serum iron level.8

Although a negative radiograph does not rule out the presence of iron from chewable, liquid, and completely dissolved iron compounds, most tablets that contain a significant amount of elemental iron are radiopaque. The presence of tablets on a radiograph correlates with the severity of the ingestion (Fig. 155-1).16,17

Management

Gastric Emptying

Iron is not bound to activated charcoal, and neither gastric lavage nor ipecac effectively removes large numbers of pills.

Iron tablets clump together as their outer coatings dissolve. Gastrostomy has been performed to remove iron from the stomach, but the success of whole-bowel irrigation generally obviates the need to consider surgery for the sole purpose of decontamination.18

For significant ingestions (>20 mg/kg of elemental iron), especially when tablets are identified on the abdominal radiograph, whole-bowel irrigation with a polyethylene glycol electrolyte lavage solution (PEG-ELS) (GoLyte, NuLytely, or GoLYTELY) is routinely recommended. The solution is either taken orally or administered through a nasogastric tube.6,19 The usual rate of administration of PEG-ELS is 20 to 40 mL/kg/hr in young children and 1.5 to 2 L/hr for teenagers or adults, continued until the rectal effluent is clear and there is no radiographic evidence of pill fragments. This technique has been used in children, adolescents, and pregnant women without serious complications or electrolyte disturbances.19,20,21 Common side effects include nausea, vomiting, abdominal cramping, and bloating. Whole-bowel irrigation is contraindicated in the presence of bowel obstruction, perforation, or ileus.12

Hemodialysis and hemoperfusion are not effective in removing iron due to its large volume of distribution. Exchange transfusions have been recommended for severely symptomatic patients with serum iron levels exceeding 1000 µg/dL.23

Deferoxamine

Deferoxamine chelates iron to form the water-soluble compound ferrioxamine, which can be renally excreted or dialyzed. One hundred milligrams will chelate 9.35 mg of elemental iron.7 Deferoxamine may also limit the entrance of iron into the cell and chelate intracellular iron. Because of its short half-life, it is administered as a continuous infusion at a dose of 15 mg/kg/hr for up to 24 hours.23 The maximum rate of administration is 35 mg/kg/hr. Rapid administration of deferoxamine can lead to hypotension, which is treated by reducing the initial rate of the infusion and slowly increasing
it to the desired rate.\textsuperscript{8} Pregnancy is not a contraindication
to deferoxamine. When calculating the dose in pregnancy, the
prepregnancy weight should be used.

The presence of ferrioxamine turns the urine a “vin rosé”
color, which reflects the excretion of chelated iron. Histori-
cally, the deferoxamine challenge test, which relied on detec-
tion of this color change, was used to diagnose the presence of
free iron in the serum. The color change is difficult to detect,
especially when the urine is dilute, resulting in false-negative
results even in cases of serious poisoning. Falsely low serum
iron values also occur in the presence of deferoxamine, so
serum iron should be measured before its administration.\textsuperscript{25}

Disposition

The asymptomatic patient who has ingested less than
20 mg/kg of elemental iron can be observed without further
therapy. If the patient remains asymptomatic after 6 hours of
observation, discharge is recommended.\textsuperscript{1}

The patient who has ingested more than 20 mg/kg of ele-
mental iron, or has pills visible on an abdominal radiograph,
should receive whole-bowel irrigation. Abdominal radiographs
can verify adequate gastrointestinal decontamination. The
serum iron should be checked 3 to 5 hours after ingestion. A
second iron level 6 to 8 hours after ingestion should be decreas-
ing. Moderate gastrointestinal toxicity can be expected with
peak levels of 300 to 500 µg/dL. If peak levels are less than
300 µg/dL, are not rising, and the patient is asymptomatic
during 6 hours of observation, the patient can be discharged
home. Patients with a serum iron level greater than 500 µg/dL
or patients with any systemic signs of toxicity (mental status
changes, shock, or high anion gap acidosis) require chelation
with deferoxamine.\textsuperscript{8}

When serum iron levels are not immediately available, ele-
vations of the serum glucose level and leukocyte count are
100% specific for predicting serum iron levels greater than
300 µg/mL. A sensitivity of 50% limits their sole use as indica-
tors of toxicity.\textsuperscript{26} However, if the results of both these tests are
normal, there are no signs or symptoms of toxicity during the
6-hour postingestion period, and the abdominal radiographs do
not show pills in the gastrointestinal tract, the patient can be
sent home.

LEAD

Lead poisoning is a disease of industrialization. It is the most
common toxicologic problem of environmental origin in the
United States.\textsuperscript{27,28} Exposure usually results from ingestion or
inhalation. Less often, it results from direct skin contact with
organic lead compounds or from retained bullets in or near
joints.\textsuperscript{29} Approximately 3 to 4 million children (1 in 20) in the
United States have toxic blood lead levels (BLLs).\textsuperscript{27,30} Although
the addition of lead to household paint and gasoline was
banned in the United States in the 1970s, lead-based paint is
still found in 30 million homes.\textsuperscript{30} Other sources of toxic lead
 ingestions include curtain weights, buckshot, fishing weights,
lead-contaminated soil or water, bootleg whiskey (“moon-
shine”), food or beverages stored or prepared in lead-soldered
cans, lead-glazed pottery, and lead crystal decanters.\textsuperscript{31} Herbal
and folk remedies, toys, and numerous products imported
from Asia and Mexico contain dangerous amounts of lead.\textsuperscript{32,33}

Children typically present to the emergency department (1)
following an ingestion of lead, (2) symptomatic with a possible
exposure history, or (3) referred for management of an ele-
vated BLL. Lead toxicity in adults most often results from
inhalational exposure in the workplace, as well as from hobbies
and related activities. It is estimated that more than 3 million
workers in the United States are at risk for toxic lead exposure
in industries such as lead smelting, battery manufacture, radi-
tor repair, bridge and ship construction or demolition, solder-
ing or welding, cable or tin can production, stained glass
manufacture, lead-glazed or crystal pottery making, glass pro-
duction, firing range operation, and lead-based paint abate-
ment.\textsuperscript{27,28} Hobbies at risk include making glazed pottery, target
shooting at indoor firing ranges, soldering lead, smelting lead
in the preparation of buckshot and fishing sinkers, repairing
cars or boats, and remodeling homes. Lead toxicity should
be considered in adults with compatible symptoms associated
with these exposures.

Principles of Disease

Pharmacology

There is no known biologic need for lead. Its absorption is
highest in malnourished children (approximately 40%) and in
pregnant women.\textsuperscript{34} Although 90 to 95% of lead is stored in
cortical bone and teeth, it is also found in the brain, liver, and
kidneys. Approximately 75% of the absorbed lead is elimi-
nated by the kidneys, with the remainder absorbed through
the skin, hair, sweat, nails, and gastrointestinal tract.\textsuperscript{20}

Pathophysiology

Lead binds to sulphydryl groups and other ligands and inter-
feres with critical enzymatic reactions.\textsuperscript{26} Its toxic effects are
most prominent in the hematopoietic, neurologic, and renal
systems.\textsuperscript{34,35}

Anemia, the classic manifestation of hematopoietic toxicity,
may be either normochromic or hypochromic. The severity of
the anemia correlates directly with the BLL. Inhibition of
heme biosynthesis results in the accumulation of heme precur-
sors such as δ-aminolevulinic acid and protoporphyrin.\textsuperscript{34} In
the peripheral nervous system, segmental demyelination and
degeneration of motor axons result in peripheral neuropa-
thies.\textsuperscript{27} Wrist drop and foot drop are characteristic of adult lead
poisoning. Lead toxicity also causes neuropsychiatric disor-
ders. In children, elevated BLLs are associated with decreased
intelligence (IQ) scores, hyperactivity, decreased attention
span, overaggressive behavior, learning disabilities, criminal
behavior, and subclinical sensorineural hearing loss.\textsuperscript{36,42} Lead
nephropathy is characterized by fibrosis in the proximal
tubules, with relative sparing of the glomeruli. Hyperuricemic
gout (“saturine gout”) can result from increased reuptake of
uric acid by the tubular cells. Lead poisoning has also been
correlated with hypertension.\textsuperscript{40} Adults and children with acute
toxicity may present with lead encephalopathy associated with
increased capillary permeability and cerebral edema.\textsuperscript{39}

Clinical Features

Symptoms of chronic, mild lead poisoning are slow in onset
and nonspecific. The diagnosis is suspected by obtaining an
accurate and comprehensive history of exposure to lead.

Acute exposure to lead can result in symptomatic poisoning.
“Lead colic” is characterized by cramping abdominal pain with
nausea, vomiting, constipation, and, occasionally, diarrhea.\textsuperscript{29}
Other characteristic symptoms and signs of acute toxicity
include fatigue, anemia, peripheral neuropathy, renal impair-
ment, and hepatic and CNS dysfunction. The CNS toxicity
may manifest as mild headache or personality changes to full-
blown encephalopathy with coma, convulsions, and papill-
edema. Permanent neurologic and behavioral sequelae may
occur.\textsuperscript{26}

### Diagnostic Strategies

Although capillary lead levels correlate well with BLLs, the most informative biomarker is a BLL. The Centers for Disease Control and Prevention has defined a chronic BLL of greater than 10 µg/dL as toxic for a child. Acute exposure can result in levels up to 100 µg/dL (Table 155-3). Other ancillary data include findings on complete blood cell count, serum glucose, blood urea nitrogen, creatinine, electrolyte levels, and urinalysis. A peripheral smear may show basophilic stippling. Markers of hepatic injury may be elevated following acute exposure. Lead-containing paints and objects are radiopaque when present in sufficient quantities, and radiographs can confirm acute ingestion and monitor the effectiveness of whole-bowel irrigation. In cases of altered mental status, seizures, or coma, a computed tomography scan of the head will show cerebral edema associated with acute lead encephalopathy and rule out other causes for these symptoms. In children, plain radiographs of the wrist and knees may show increased metaphyseal activity manifest as “lead bands” or “lead lines” that are characteristic of chronic exposures.

### Management

#### Acute Lead Encephalopathy

Acute lead encephalopathy can be rapidly fatal. The initial goals in management are to identify and treat all life-threatening conditions, followed by efforts to prevent further exposure to lead, minimize absorption of ingested lead, enhance its elimination, and prevent or reverse cellular pathology. Standard measures to control cerebral edema, including intubation and neurosurgical consultation for invasive monitoring of intracranial pressure, are indicated. When a severe poisoning is associated with ingestion or if radiopacities are seen on the radiograph, decontamination with whole-bowel irrigation is indicated. Activated charcoal does not adsorb lead.

### Chelation Therapy

The use of chelation in cases of acute lead poisoning is guided by the patient’s clinical status and the BLL. Any patient with a BLL greater than 70 µg/dL, or with signs suggestive of encephalopathy, will require admission for parenteral chelation therapy. For these seriously poisoned patients, dimercaprol (or British antilewisite [BAL]) should be the first chelator given. The dosage is 3 to 5 mg/kg (25 mg/kg/day), given by deep intramuscular injection every 4 hours for 2 days, followed by a dose every 4 to 6 hours for 2 more days and then every 4 to 12 hours for up to 7 days. Dimercaprol forms complexes that undergo both renal and biliary excretion. Adverse reactions to dimercaprol include nausea, vomiting, urticaria, pyrexia, hypertension, and hemolysis in patients with glucose-6-phosphate dehydrogenase deficiency. Since dimercaprol is diluted in peanut oil, it is contraindicated in patients allergic to peanuts. Dimercaprol is followed by calcium disodium ethylenediaminetetraacetic acid (CaNa₂EDTA), a highly effective lead chelator. Because of concerns that the chelated lead can cross the blood-brain barrier and worsen encephalopathy, the first dose of CaNa₂EDTA is administered with the second dose of dimercaprol. The dosage of CaNa₂EDTA for patients with acute lead encephalopathy is 75 mg/kg/day or 1500 mg/m²/day given intravenously or intramuscularly in two to four divided doses, with a maximum daily dose of 1 g in children and 2 g in adults. Adverse reactions include renal tubular injury and chelation of other metals, especially iron and zinc. CaNa₂EDTA should be given only with adequate urine flow or with hemodialysis in the patient with renal failure. It is important that CaNa₂EDTA not be confused with sodium (Na) EDTA. The administration of NaEDTA has been associated with hypocalcemia and death from arrhythmias.

The need for parenteral chelation therapy in asymptomatic or minimally symptomatic children is guided by the BLL. A BLL of more than 69 µg/dL mandates hospitalization and parenteral chelation therapy. For less seriously poisoned patients, the dosage of CaNa₂EDTA is 50 mg/kg/day or 1000 mg/m²/day, given in two to four divided doses for up to 5 days.

Serum lead levels of 45 to 69 µg/dL in patients without vomiting or CNS symptoms can be managed in the outpatient setting using oral succimer (2,3-dimercaptosuccinic acid [DMSA]; Chemet). The initial dose of DMSA is 10 mg/kg every 8 hours for 5 days, then 10 mg/kg every 12 hours for 14 days. The most common adverse reactions include nausea, vomiting, diarrhea, and transient elevations in liver transaminase levels. Although DMSA has been approved only for children, it is also used in adults. Oral D-penicillamine should be used only in patients who do not tolerate succimer. The usual oral dose of D-penicillamine is 25 mg/kg every 6 hours for 5 days. D-Penicillamine is less efficacious than succimer and has more adverse reactions. Penicillin allergy is a contraindication to the use of D-penicillamine.

The key to managing chronic lead toxicity is the identification and reduction of sources of primary exposure. Any patient treated on an outpatient basis must be discharged to a lead-free environment. A BLL between 20 and 44 µg/dL in a patient who is asymptomatic or minimally symptomatic requires a more aggressive medical and environmental evaluation. Evidence indicates no need for chelation for children with a BLL lower than 45 µg/dL. Children with lead levels of 10 to 19 µg/dL require family counseling about the symptoms and sources of lead exposure and careful follow-up, with frequent screening of BLLs.

The treatment of adults with chronic poisoning is less aggressive than for children. If gastrointestinal symptoms or...
CNS problems are present, hospitalization with parenteral chelation therapy is indicated. In the asymptomatic adult or the adult with only mild clinical problems, the only intervention needed is cessation of exposure. According to the Occupational Safety and Health Administration lead standard, workers with serum lead levels greater than 50 µg/dL must be removed from work.56

Disposition

Patients who have ingested a single lead foreign body (e.g., fishing sinker) will usually pass it harmlessly.57 If the foreign body remains in the gastrointestinal tract after 2 weeks, removal should be considered to prevent lead toxicity.

Patients who are significantly symptomatic after an acute lead exposure and children with a BLL of 69 µg/dL or greater require hospitalization and chelation therapy. Patients discharged home on oral chelation therapy should not return to a contaminated environment. The health department should conduct an environmental assessment so that the primary source of lead exposure can be identified and further exposure prevented. Follow-up should be arranged with an experienced pediatrician, toxicologist, or occupational medicine physician.58

■ ARSENIC

Arsenic (As), a tasteless, odorless substance that looks like sugar, has an infamous history as an agent of homicide. Arsenic has also been implicated in many incidences of epidemic poisoning. Currently, arsenic exposure is primarily environmental and occupational. It is found in smelters and electric power plants that burn arsenic-rich coal. It is used in industry as a wood preservative and in the production of glass and microcircuits. Inorganic arsenicals are also used in rodenticides, fungicides, insecticides, paint, and tanning agents and as defoliants in the cotton industry. Arsenic is still used for medicinal purposes in the treatment of trypanosomiasis, amebiasis, and leukemia.59 It has also been found as a contaminant in herbal remedies and drugs such as opium.60 There are widespread reports of chronic arsenic poisoning associated with contaminated drinking water in underdeveloped countries.61 Arsenic poisoning should be suspected if compatible symptoms occur with the use of these products or these possible exposures.

Principles of Disease

Pharmacology

Arsenic has no metabolic or biologic function. The elemental metal is poorly water soluble and is considered nontoxic. Of the two inorganic forms, trivalent arsenite (As³⁺) is highly lipid soluble and is 5 to 10 times more toxic than the pentavalent arsenate (As⁵⁺) form. The more toxic lipophilic trivalent arsenite form has a lower gastrointestinal absorption but is well absorbed by the skin. The pentavalent arsenate form, although less toxic, is water soluble and readily absorbed from the gastrointestinal tract. Absorbed arsenic is bound by hemoglobin, leukocytes, and plasma proteins. It is cleared from the intravascular compartment within 24 hours and concentrates in the liver, kidneys, spleen, lungs, and gastrointestinal tract. Arsenic crosses the placenta and can also accumulate in the fetus. Its affinity for sulfhydryl groups in keratin makes arsenic detectable in the hair, skin, and nails.62 Arsine (AsH₃), a colorless and almost odorless gas, is extremely toxic.63 It is immediately lethal at 250 ppm.64 The excretion of arsenic and its metabolites occurs mainly through the kidneys.

Pathophysiology

Arsenic binds avidly to sulfhydryl groups, inhibiting critical enzymes such as lactate dehydrogenase and glyceraldehyde-3-phosphate dehydrogenase, a critical step in glycolysis. It also disrupts oxidative phosphorylation by replacing phosphorus in the formation of high-energy phosphate bonds (arsenolysis).59 Arsine causes massive hemolysis. The exact mechanism is poorly understood.65

Clinical Features

Acute exposure to arsenic gas is characterized by severe hemolysis that is associated with renal tubular injury. Gastrointestinal symptoms are common, and CNS and liver dysfunction can occur. The mortality rate is 25 to 30%. Exchange transfusions and plasma exchange have been used to remove arsine, which is tightly bound to the erythrocytes.66 Urinary alkalinization can be used to decrease renal deposition of hemoglobin.

Acute gastrointestinal effects—nausea, vomiting, abdominal pain, and diarrhea—predominate as the initial manifestations of acute exposure to arsenic salts.59,66-68 These symptoms can be so severe as to result in hematemesis and hematochezia. Within 30 to 60 minutes of exposure, patients complain of a metallic or garlicky taste. The patient can also develop encephalopathy with seizures and coma, respiratory failure associated with acute respiratory distress syndrome, and dysrhythmias associated with cardiac conduction disturbances.69-71 In cases of severe poisoning, cardiovascular collapse and death ensue.72 Less common complications include hepatitis, rhabdomyolysis, hemolytic anemia, renal failure, unilateral facial nerve palsy, pancreatitis, pericarditis, pleuritis, and fetal demise (Box 155-1).68 The syndrome may be misdiagnosed as gastrointestinal or sepsis.

Weeks to months after the initial symptoms, chronic effects of arsenic poisoning appear, including characteristic lines in the nails (Mees’ lines), painful sensorimotor neuropathy, and hyperkeratosis of the palms and soles.59 Arsenic poisoning should also be considered in any patient with a history of severe or recurrent gastroenteritis/abdominal pain and unexplained dermatologic lesions associated with peripheral neuropathy. Finally, arsenic is a known human carcinogen.59

Diagnostic Strategies

Normal arsenic levels are 5 µg/L or less in blood or less than 50 µg/day in a 24-hour urine collection, which is the best way to diagnose the poisoning. Any urine level above 100 µg/day or 50 µg/L necessitates treatment. A spot urine sample may be falsely low because urinary excretion of arsenic is intermittent. Seafood contains arsenobetaine, which can increase urinary arsenic excretion to as high as 1700 µg/L.73 Arsenobetaine, however, does not result in arsenic toxicity. For this reason, patients should refrain from eating seafood prior to testing whenever feasible, or the laboratory should be asked to speciate the type of arsenic measured.74

Other laboratory results may raise the suspicion of arsenic poisoning in the right clinical setting. Anemia, leukocytosis or leukopenia, and erythrocyte basophilic stippling are seen in the complete blood cell count. The results of renal function tests may be abnormal. Proteinuria, hematuria, and pyuria are also seen. The alanine aminotransferase, aspartate aminotransferase, and bilirubin levels may be elevated. In cases of chronic arsenic poisoning, the serum and urine arsenic levels may be undetectable, whereas hair and nail specimens can confirm the diagnosis.
Acute Effects of Arsenic Poisoning

**Gastrointestinal**
- Violent gastroenteritis
- Hematemia/hematocritia
- Jaundice
- Pancreatitis
- Dysphagia
- Hepatomegaly

**Cardiovascular**
- Third spacing with shock
- Sinus/ventricular tachycardia
- Prolonged QT interval, ST depression, T wave inversion
- Torsades de pointes
- Pericarditis

**Respiratory**
- Respiratory failure
- Adult respiratory distress syndrome
- Pulmonary edema
- Pneumonia

**Renal**
- Proteinuria
- Hematuria
- Oliguria
- Renal failure

**Neurologic**
- Headache
- Drowsiness
- Delirium
- Coma
- Encephalopathy
- Seizures

Arsenic in the gastrointestinal tract is radiopaque and can appear on a radiograph, although sensitivity is limited by rapid absorption and the ensuing gastroenteritis.75

**Management**

The initial management should address life-threatening conditions with supportive management of shock, dysrhythmias, and seizures. Activated charcoal does not adsorb arsenic and is of no value. Although there is no evidence for improved outcomes, orogastric lavage or whole-bowel irrigation should be considered only for very recent (<1 hr) ingestions or if radiopaque material is visualized on an abdominal radiograph. Hemodialysis removes arsenic in the setting of acute renal failure.73 Exchange transfusions or plasma exchange should be considered very early after an arsine exposure.73

With a known history of exposure in a symptomatic patient, chelation should start as early as possible without waiting for laboratory confirmation of the arsenic levels. Intramuscular dimercaprol is the preferred chelator in patients who are critically ill. DMSA is a water-soluble analogue of dimercaprol that can be given orally.76,77 D-Penicillamine has a high side effect profile, and its ability to chelate arsenic is inferior to that of dimercaprol and DMSA. Therefore, it should only be used when both dimercaprol and DMSA are unavailable. All patients receiving chelation for acute arsenic toxicity should be admitted. Chelation is not useful for arsenic exposures.

Sources of Mercury

**Elemental**
- Spill from mercury-containing devices
- Gastrointestinal exposure from ruptured Cantor or Miller-Abbott tube
- Inhalational exposure in the workplace/home
- Deliberate injection or ingestion
- Accidental ingestion

**Salts**
- Accidental disk battery ingestion
- Deliberate ingestion
- Laxative abuse

**Organic**
- Oral/dermal exposure to mercurochrome or thimerosal
- Repeated injections of drugs containing thimerosal as a preservative
- Exposure from occupational or agricultural accidents
- Water/soil pollution
- Consumption of contaminated seafood
- Exposure to paint containing mercury

**Mercury**

Mercury is a silver white metal, familiar to most as the only metal that is liquid at room temperature. It has a long history of medicinal uses as an antiparasitic, a diuretic, a cathartic, an antiseptic, and as a preservative in many vaccines.78 Significant poisoning in the home has occurred when relatively small amounts of spilled mercury, such as that contained in a sphygmomanometer, were aerosolized by vacuuming or when mercury was heated on the kitchen stove to extract gold from ore.79,80 Various other sources of mercury have also been implicated in intoxication (Box 155-2). Because of many industrial uses that include the manufacture of fluorescent lights, batteries, polyvinyl chloride, and latex paint, mercury is a common pollutant of air and water. This has led to restrictions in the consumption of fish caught in many local waters.81,82

**Principles of Disease**

**Pharmacology**

The most familiar form of mercury is elemental or metallic mercury, also known as “quicksilver.” A common route of exposure to elemental mercury is the inhalation of volatilized vapor.83 Aspiration of elemental mercury and intentional subcutaneous and intravenous injections also cause poisoning.84 After inhalation, 74% of the metallic mercury is retained in the lungs. This can result in severe pneumonitis and acute respiratory distress syndrome.85 Aspiration of elemental mercury results in primary pulmonary toxicity, in addition to CNS and renal toxicities.86 Elemental mercury is not absorbed by the gastrointestinal tract, so ingestion does not normally lead to systemic toxicity unless it becomes trapped in diverticulae. Mercury is absorbed through the skin at 1% of the rate of inhaled mercury and is not a concern.

Inorganic mercury salts have two different valences, Hg1+ (mercurous) and Hg2+ (mercuric). Ingestion of either salt leads to significant gastrointestinal and renal toxicity.

The organic mercury compounds are categorized as either short chain (alkyl) or long chain (aryl). The major route of exposure to this type of mercury is through ingestion, but these compounds are also readily absorbed through the skin. These
organic forms classically result in delayed neurotoxicity with prominent ataxia, tremor, dysarthria, and tunnel vision.82,87

**Pathophysiology**

Mercury binds covalently to sulphydryl groups, disturbing multiple cellular enzyme functions. Nephrotoxicity results from both direct damage and an immune reaction in the kidney.79 The skin changes associated with mercury poisoning are also caused by an immune reaction. Mercury increases catecholamine levels by inhibition of catechol-O-methyltransferase, resulting in hypertension and tachycardia.88,89 Atrophy of the brain correlates with the symptoms of ataxia, sensory, and visual field disturbances.90

**Clinical Features**

The clinical manifestations of mercury poisoning depend on the acuity of the exposure, the route of exposure, and the chemical form of mercury. Inhalation of elemental mercury vapor results in the rapid onset of shortness of breath, fever, and chills that progresses to pneumonitis and respiratory distress.80,85,91 Aspiration of liquid metallic mercury during medical procedures results in the rapid onset of tracheobronchial hemorrhage.92

Ingestion of inorganic mercury salts typically causes a corrosive gastroenteritis with third spacing and hemorrhage. Patients complain of a metallic taste in the mouth and may have a grayish discoloration of the mucous membranes. Massive fluid loss results in shock and acute tubular necrosis. The manifestations of subacute or chronic inorganic mercury poisoning are neurologic (e.g., neurasthenia and erethism), renal (ranging from proteinuria to the nephrotic syndrome), and gastrointestinal (e.g., metallic taste, gingivostomatitis, loose teeth, burning sensation in mouth, hypersalivation, and nausea).79,93

Exposure to organic mercury compounds is not associated with acute toxicity. Neurologic symptoms develop over weeks to months. The neurologic and teratogenic effects of chronic exposure to methylmercury were well illustrated by the tragic poisoning of the population of Minamata, Japan, by fish caught in mercury-polluted water.94 Slowly progressive fatal CNS injury was described following a minor topical exposure to dimethylmercury in a laboratory researcher (Table 155-4).81,87,95

**Diagnostic Strategies**

Measurement of urine mercury levels is the most helpful test in confirming exposure and monitoring the effectiveness of chelation. For organic mercury compounds, which undergo little urinary excretion, serum levels must be used to confirm the diagnosis. “Normal” mercury levels are considered to be less than 10 µg/L in the blood or less than 20 µg/L in the urine. Blood levels greater than 35 µg/L and urine levels greater than 150 µg/L require intervention. No information is available on chelation at levels between 20 and 150 µg/L. Metallic mercury is radiopaque on plain radiographs, which can be ordered in cases of injection or ingestion of metallic mercury.84

**Management**

Initial management in the acutely poisoned patient should be aggressive support and decontamination. Gastric lavage with protein-containing solutions (e.g., milk and egg whites) may be beneficial in the decontamination of the gastrointestinal tract following ingestion of mercury salts. This is based on case reports only. Charcoal adsorbs very little mercury and is not recommended unless another serious co-ingestant is suspected. Ingested metallic mercury is generally harmless unless its passage is impaired by entrapment in a diverticulum or the appendix.96

For acute inhalational exposures, the patient should be removed from the source and supportive management provided. There is no role for prophylactic antibiotics or steroids. Suction and postural drainage are indicated in cases of acute aspiration of metallic mercury. Self-injection of metallic mercury often requires surgical débridement of infiltrated tissue.84

Help in the management of mercury spills can be obtained from the local hazardous materials team and the local health department.85 Information on handling mercury spills can also be found at the Environmental Protection Agency website at http://www.epa.gov/hg/spills/index.htm. Sand or mercury decontamination kits that contain calcium polysulfide, which converts mercury to mercuric sulfide, should be used. Absorbable surfaces such as carpets should be removed. Attempts to remove mercury by vacuuming can volatilize the mercury and precipitate acute inhalational toxicity. Small spills, such as the contents of a home thermometer or a fluorescent bulb (amount = 30 ml or two tablespoons), can be scooped up with a stiff card or aspirated into a dropper placed onto a damp paper towel, sealed in a plastic bag, and ideally disposed of as hazardous waste. Mercury placed in household trash is incinerated and contributes to soil and water pollution and, ultimately, accumulation in the food chain.

**Chelation Therapy**

Chelating agents have thiol groups that compete with the enzyme sulphydryl groups that bind mercury. BAL is used for

ARDS, acute respiratory distress syndrome.
clinically significant acute inorganic mercury intoxication. Because it increases brain mercury levels in patients with methylmercury poisoning, BAL is contraindicated for patients poisoned with organic mercury compounds. Although DMSA is not currently approved by the U.S. Food and Drug Administration for this indication, it is used for both acute and chronic mercury poisoning and may be the best chelator for methylmercury. n-Penicillamine is also used. It should be administered only after thorough gastrointestinal decontamination because mercury absorption from the intestinal lumen is enhanced by the penicillamines.

Disposition

In general, in cases of acute intoxication, the most toxic forms are the inorganic mercurials. Suicidal patients with such ingestions require decontamination and admission for supportive treatment. Patients who self-inject metallic mercury often need admission for surgical débridement. Patients with signs of neurotoxicity from an organomercurial also need admission. Most asymptomatic individuals can be followed closely with urinary testing as outpatients.

KEY CONCEPTS

- Ingestion of the salts of most metals causes severe gastrointestinal pain and emesis.
- Chelation with acute iron ingestion is guided by symptoms and two serum iron levels measured between 3 and 8 hours after ingestion.
- Patients with symptomatic acute lead exposures require immediate chelation. Asymptomatic or minimally symptomatic children with elevated BLLs require close follow-up and possible outpatient chelation. Parenteral chelation is indicated in children with lead levels greater than 69 µg/dL.
- Patients with a possible chronic heavy metal exposure and compatible symptoms should have further investigation and close follow-up.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
Human exposure to hydrocarbons (HCs) is a common problem. U.S. poison centers report 50,000 HC exposures annually, with the majority handled in an outpatient setting. HC exposures that present to the emergency department (ED) generally can be classified into four types. The first is accidental ingestion involving children younger than age 5 years. This is the most common scenario causing fatality, and it usually involves significant pulmonary injury. Second is intentional inhalational abuse of volatile HCs. Recreational abuse has been a medical problem since solvent inhalation became popular during the late 1800s. Fatalities in this group will typically occur within distinct demographic groups (American Indians, homosexual males, and teenagers). Third is accidental inhalational or dermal exposure to HC in the household or workplace setting. The fourth type is massive oral ingestion of HC in a suicide attempt.

**Definitions and Terminology**

HCs are a diverse group of organic compounds that contain hydrogen and carbon (Table 156-1). Most HCs (e.g., gasoline) are by-products of crude oil and are therefore called petroleum distillates. Some products, such as turpentine, are derived from pine oil, not petroleum. HCs can also be classified by their structure. The two main categories are straight chain HCs (aliphatic, such as propane) and those containing a benzene ring structure (aromatic, such as toluene). HCs can also have multiple nonorganic side chains. For example, halogenated HCs (e.g., carbon tetrachloride) usually will have one or more bromide, chloride, fluoride, or iodide moieties. Finally, HCs are used as the solvent base for many toxic chemicals such as insecticides and metals that in turn can cause a separate type of poisoning. Although the range of toxicity of HCs can vary widely, the majority of human exposures are confined to petroleum distillates.

**Pathophysiology**

Acute HC toxicity usually affects three main target organs: the lungs, the central nervous system (CNS), and the heart. Although certain HCs can enter the body through the skin or gastrointestinal (GI) tract, HCs cause the most damage via the lungs. Despite the fact that there are thousands of different types of HCs, their potential for acute toxicity depends mainly on four characteristics:

1. **Viscosity** is the capacity to resist flow or change. Low viscosity allows a substance to spread rapidly, and a low-viscosity HC spreads easily into the airway and lungs. Thus, the lower the viscosity, the higher the toxicity. Viscosity is measured in Saybolt Seconds Universal (SSU), and substances with an SSU of less than 60 have the highest potential risk of aspiration. Lubricants and mineral oil have high viscosity and low toxicity, whereas furniture polish has low viscosity and high toxicity.
2. **Volatility** is the ease for a liquid to turn into a gas. High volatility gives an odor and enables a substance to displace alveolar oxygen. Butane and gasoline are types of HCs with high volatility.
3. **Surface tension** is the capacity for a substance to collect on a liquid surface. Low surface tension enables a substance (e.g., turpentine) to disperse easily.
4. **Chemical side chains** often increase potential toxicity. These toxic side chains include metals (e.g., arsenic), halogens (e.g., carbon tetrachloride), and aromatic structures (e.g., toluene).

**Pulmonary Pathophysiology**

The primary organ of toxicity for HCs is the lung. Fatalities after ingestion usually occur with an accompanying aspiration. Studies have shown that pulmonary toxicity is caused by aspiration rather than by GI absorption and hematogenous spread. A small amount of an HC in the trachea can be devastating, whereas a much larger amount of the same compound in the stomach can be benign.

HCs affect the lungs through several mechanisms. HCs are usually poorly water soluble and are thereby able to penetrate into the lower airways, producing bronchospasm and an inflammatory response. Second, volatized HCs can displace oxygen in the alveolar space causing hypoxia. Third, HCs can cause direct injury to pulmonary alveoli and capillaries, producing distinct uniform lesions. Autopsy findings of these lesions include hyperemia, diffuse hemorrhagic exudative alveolitis with granulocytic infiltration, and microabscesses. Finally, HCs can inhibit surfactant function leading to alveolar instability and collapse. These mechanisms lead to alveolar dys-
function, ventilation perfusion mismatch, hypoxemia, and respiratory failure.5,7

Central Nervous System Pathophysiology

Certain HCs cause CNS depression (i.e., toluene, benzene, gasoline, butane, and chlorinated HCs). After respiratory exposure, most HCs passively diffuse through the pulmonary alveolus and are highly absorbed in blood and tissues. These HCs can cause euphoria, disinhibition, confusion, and obtundation. With an isolated single exposure, these effects usually have a rapid onset of intoxication and rapid recovery. For these reasons, substance abusers seek these HCs for recreational use. Inhalation of these substances avoids hepatic first-pass metabolism and generates high concentrations in the CNS. Chronic use of inhaled HCs can cause severe abnormalities in nervous system function, which include peripheral neuropathy, cerebellar degeneration, neuropsychiatric disorders, chronic encephalopathy, and dementia. More than 50% of patients who abuse toluene for more than 10 years will have cerebral cortical atrophy with histologic changes that include loss of neurons, diffuse gliosis, and axonal degeneration.5,8

Cardiac Pathophysiology

HCs can cause sudden death, especially after intentional inhalation. These compounds are thought to produce myocardial sensitization of endogenous and exogenous catecholamines, which then precipitates ventricular dysrhythmias and myocardial dysfunction. This is particularly true for halogenated and aromatic HCs (e.g., difluoroethane found in computer keyboard cleaning canisters).9,10

Other Pathophysiology

Various HCs have been reported to be toxic to other organ systems. Certain recognized syndromes include toluene-induced renal tubular acidosis, benzene-induced bone marrow toxicity and leukemia, methylene chloride–induced carbon monoxide poisoning, and chlorinated HC–induced centrilobular hepatic necrosis and renal failure. Direct skin exposure of certain HCs can cause extensive chemical burns.5,17 HCs are often used as solvents for other chemicals that may have their own significant inherent toxicity.

---

**Central Nervous System Pathophysiology**

Certain HCs cause CNS depression (i.e., toluene, benzene, gasoline, butane, and chlorinated HCs). After respiratory exposure, most HCs passively diffuse through the pulmonary alveolus and are highly absorbed in blood and tissues. These HCs can cause euphoria, disinhibition, confusion, and obtundation. With an isolated single exposure, these effects usually have a rapid onset of intoxication and rapid recovery. For these reasons, substance abusers seek these HCs for recreational use. Inhalation of these substances avoids hepatic first-pass metabolism and generates high concentrations in the CNS. Chronic use of inhaled HCs can cause severe abnormalities in nervous system function, which include peripheral neuropathy, cerebellar degeneration, neuropsychiatric disorders, chronic encephalopathy, and dementia. More than 50% of patients who abuse toluene for more than 10 years will have cerebral cortical atrophy with histologic changes that include loss of neurons, diffuse gliosis, and axonal degeneration.5,8

**Cardiac Pathophysiology**

HCs can cause sudden death, especially after intentional inhalation. These compounds are thought to produce myocardial sensitization of endogenous and exogenous catecholamines, which then precipitates ventricular dysrhythmias and myocardial dysfunction. This is particularly true for halogenated and aromatic HCs (e.g., difluoroethane found in computer keyboard cleaning canisters).9,10

**Other Pathophysiology**

Various HCs have been reported to be toxic to other organ systems. Certain recognized syndromes include toluene-induced renal tubular acidosis, benzene-induced bone marrow toxicity and leukemia, methylene chloride–induced carbon monoxide poisoning, and chlorinated HC–induced centrilobular hepatic necrosis and renal failure. Direct skin exposure of certain HCs can cause extensive chemical burns.5,17 HCs are often used as solvents for other chemicals that may have their own significant inherent toxicity.

**CLINICAL FEATURES: SYMPTOMS AND SIGNS**

There are several typical life-threatening clinical presentations of acute HC exposures. The first scenario is a child who has ingested an unknown quantity of an HC. Significant life-threatening poisonings usually have early respiratory symptoms, including cyanosis, coughing, grunting, noisy respirations, or repeated bouts of vomiting. These findings suggest aspiration. A patient may initially have mild symptoms and then develop tachypnea, dyspnea, bronchospasm, wheezing, rales, and fever within 6 hours.12,18 A change in mental status can be a manifestation of hypoxia or hypercapnia, but it is also a direct effect of HCs. In extreme cases, these patients may present with frank respiratory failure. Additives or solutes in
the HC base can produce varying symptoms (e.g., seizures from camphorated hydrocarbons or cyanosis from nitrite-induced methemoglobinemia). Pesticides are a classic example of such a toxic substance that is often placed in an HC base. With pesticide exposures, it can be very difficult to distinguish acute respiratory distress syndrome induced by HC aspiration from pulmonary edema induced by organophosphate exposures.

The second scenario is the solvent-abusing adolescent or adult. In the extreme case, these patients will be in cardiac arrest. Nonhospital medical personnel often describe an individual who has inhaled solvents, performed some type of physical activity, and then suddenly collapsed. This is thought to be due to cardiac sensitization by endogenous catecholamine and the ensuing development of dysrhythmias. Various paraphernalia commonly include plastic bags used for “bagging” (a method of pouring HCs in a bag or container and then inhaling deeply) or an HC-soaked cloth used for “huffing” (a method in which abusers inhale through a saturated cloth). Other paraphernalia include gasoline containers, multiple butane lighters, and spray paint cans. These patients often have a distinctive odor because almost all of these products are volatile. They may have paint or a rash over the mouth and nose (“glue-sniffer’s rash”) (Fig. 156-1). These patients can also present to the ED with CNS intoxication comprising euphoria, agitation, hallucinations, confusion, and bizarre behavior. This may progress to CNS depression and seizures. Drug abusers who chronically inhale HCs may not be brought to medical attention specifically for treatment of their drug abuse but, rather, for behavioral problems or nonspecific medical symptoms caused by their abuse. The long-term chronic abuser may clinically appear similar to the long-term “skid row” alcoholic, with peripheral neuropathy, cerebellar degeneration, and encephalopathy.

A third common scenario is the accidental dermal or inhaled (nonaspiration) respiratory exposure to HCs in the workplace or home. Fortunately, this is rarely life-threatening. Most cases do not seek medical care or are handled primarily through local poison control centers. A very small percentage will seek treatment in the ED. Most of these patients will either be asymptomatic or have transient nonspecific symptoms such as headache, dizziness, or nausea. Those with significant respiratory exposure may have persistent pulmonary complaints and physical findings such as coughing, wheezing, and cyanosis. Patients with significant acute dermal exposures may have pain and evidence of chemical burns consisting of erythema, swelling, blistering, and dermal destruction.

The patient who intentionally ingests or intravenously injects HCs in a suicide attempt is rare. However, these patients can be difficult to treat because HCs are often ingested in combination with other substances. In the absence of aspiration or co-ingestion of another toxic substance, the massive oral ingestion of most commonly available HCs is not associated with significant morbidity or mortality. These patients risk aspiration if they vomit.

**DIAGNOSTIC STRATEGIES**

The diagnosis of HC poisoning is made on clinical grounds. In all cases, nonhospital medical personnel, family, and bystanders should be encouraged to bring the offending agent to the ED. The local poison control center may help to identify and verify substances containing HCs. When verification of an unknown substance is required, a reference laboratory is usually needed. Laboratory identification of HCs is usually time-consuming and not helpful in the ED management.

History and examination should focus on possible aspiration. These symptoms include cough, difficulty breathing, or shortness of breath. Signs of a significant exposure include tachypnea, tachycardia, wheezing, and hypoxemia. Patients with a significant HC exposure should have a chest radiograph taken. Radiographic changes can occur within 30 minutes of ingestion and may identify pathology not recognized by auscultation in more than 50% of cases. Continuous pulse oximetry and arterial blood gases may also be helpful.

Patients who chronically abuse HCs often go to the ED for behavioral problems or nonspecific symptoms caused by their drug addiction. Similar to the intoxicated chronic alcoholic who is a common ED patient, these patients require close medical scrutiny to exclude underlying or secondary diseases. For example, chronic toulene abusers can develop acid-base disorders and indicate a need to measure electrolytes, blood urea nitrogen, creatinine, and urinalysis.

**DIFFERENTIAL CONSIDERATIONS**

In the most common fatal scenario—the child who ingests and then aspirates HC—the physician should be sure that no other toxic substances are involved. Organophosphate, salicylate, and paraquat poisonings can mimic the symptoms of HC aspiration. In the scenario of the recreational abuser, multiple drugs of abuse may be present. Behavioral disorders and confusion can be caused by hypoxia and respiratory compromise as well as from the drugs themselves. In the chronic abuser, it can be difficult to differentiate between a functional and an organic confusional state.

**MANAGEMENT**

Dermal exposures of HCs can cause extensive burns, and exposed patients should be decontaminated immediately. Contaminated clothing should be removed, and the skin should be washed with soap and copious lukewarm water. The GI decontamination of ingested HCs is controversial. The aphorism “the safest place in the body for hydrocarbons is the duodenum” holds true for most HCs regardless of the volume ingested. Routine gastric lavage or emesis should be avoided because HCs are much more toxic to lungs than to...
the GI tract, where they also have a low potential for systemic absorption. Efforts at decontamination after the ingestion of a benign HC can result in aspiration, thereby converting a relatively nontoxic ingestion to a toxic aspiration. In certain situations, GI decontamination may be indicated. This is due to either the inherent toxicity of the HC or the toxicity of additives to the HC. A well-publicized mnemonic to describe most of these cases is CHAMP:

C—camphor, which can cause seizures and status epilepticus
H—halogenated HC, which can cause dysrhythmias and hepatotoxicity
A—aromatic HC, which can cause bone marrow suppression and cancer
M—metals (e.g., arsenic, mercury, and lead)
P—pesticides, which can cause cholinergic crises, seizures, and respiratory depression

Although the method of decontamination is controversial and there is scant literature to support the effectiveness of GI decontamination, use of a small-caliber nasogastric tube to evacuate stomach contents can be considered.13,21

Because HCs can cause sudden decompensation in a patient’s pulmonary, cardiac, and CNS functions, all patients should be monitored with cardiac monitors and pulse oximeters in a well-observed area. In severe cases, early intubation for airway control and positive end-expiratory pressure have been advocated by several authors to minimize aspiration risks and counteract HC-induced alveoli collapse. However, no studies have proven this to be more beneficial than standard respiratory care. High-frequency jet ventilation and extracorporeal membrane oxygenation have both been used to treat children with respiratory failure secondary to aspiration.22-25 Surfactant therapy has also been considered in these cases, but its benefit remains unproven.6 Corticosteroids and antibiotics have not been shown to be beneficial in HC aspiration, but the differentiation between bacterial and chemical pneumonia may be difficult.27 More than 50% of children with significant HC poisoning will develop a fever and leukocytosis.13,15 Epinephrine and isoproterenol should be avoided unless required for cardiac resuscitation. Theoretically, exogenous catecholamine can cause dysrhythmias in HC-sensitized myocardium.

In most cases of HC ingestion or inhalation, supportive care and close observation and monitoring are the cornerstone of management. Currently, there are no specific antidotes for HCs.

**DISPOSITION**

Patients with exposures of known, relatively benign HCs should have a 4- to 6-hour period of observation. Patients who have ingested HCs and do not have symptoms should be monitored for a minimum of 6 hours with a reassessment that may include repeat physical examination, pulse oximetry, arterial blood gas measurements, and chest radiograph during the last hour of observation (Fig. 156-2). Any evidence of symptoms at this time mandates hospital admission and further observation. Asymptomatic patients with accidental exposures to HCs can be discharged after a period of observation with appropriate follow-up.12

Patients who have ingested HCs and have symptoms suggestive of aspiration should be admitted for a minimum of 24 hours for observation. Patients who present after an episode of recreational HC use should also be observed for 4 to 6 hours. All patients in this category should be offered drug addiction counseling.3

![Figure 156-2. Chest radiograph of a patient with hydrocarbon ingestion 6 hours after exposure.](image)

**KEY CONCEPTS**

- The major toxic risk is with aspiration.
- Routine GI decontamination of HCs should be avoided.
- Symptoms can be delayed by several hours, so asymptomatic patients should be observed for an appropriate amount of time and given clear discharge instructions.
- Solvent-abusing patients are at risk for sudden cardiovascular collapse with exertion and should be kept calm and quiet.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
Airborne toxins typically produce local noxious effects on the airways and lungs. The respiratory tract can also serve as a portal of entry for systemic poisons. Inhalational exposure can be covert and indolent (as in occupational exposure to asbestos or urban exposure to photochemical smog) or fulminant and obvious. The circumstances and location of the exposure, the presence of combustion or odors, and the number and condition of victims assist in the diagnosis. Despite the array of possible toxic inhalants, identification of a specific inhalant is generally unnecessary because therapy is based primarily on the clinical manifestations (Table 157-1).

**SIMPLE ASPHYXIANTS**

**Perspective**

The vast majority of simple asphyxiants are workplace related and usually occur during the use of liquefied gas, while breathing through airline respirators or while working in confined spaces. Since the advent of catalytic converters, most deaths from the intentional inhalation of automotive exhaust result from simple asphyxiation and not carbon monoxide poisoning.

**Principles of Disease**

Most simple asphyxiants are inert and produce toxicity only by displacing oxygen and lowering the fraction of inspired oxygen (FiO₂). Exposed patients remain asymptomatic if the FiO₂ is normal. Carbon dioxide and nitrogen, both constituents of air, produce narcosis at elevated levels, but their predominant toxic effect is simple asphyxiation.

**Clinical Features**

Acute effects occur within minutes of onset of asphyxia and are the manifestations of hypoxia. A fall in the FiO₂ from normal, 0.21 (i.e., 21%), to 0.15 results in autonomic stimulation (e.g., tachycardia, tachypnea, and dyspnea) and cerebral hypoxia (e.g., ataxia, dizziness, incoordination, and confusion). Dyspnea is not an early finding because hypoxemia is not as potent a stimulus for this sensation as hypercarbia. Lethargy from cerebral edema is expected as FiO₂ falls below 0.1 (10%), and life probably cannot be sustained at an FiO₂ below 0.06 (6%). Since removal from exposure terminates the hypoxia and results in clinical improvement, most patients present with resolving symptoms. However, failure to improve suggests complications of ischemia (e.g., seizures, coma, and cardiac arrest) and is associated with a poor prognosis.

**Diagnostic Strategies and Differential Considerations**

A consistent history, an appropriate spectrum of complaints, and rapid resolution on removal from exposure are generally sufficient to establish the diagnosis. Minimally symptomatic or asymptomatic patients do not require chest radiography or arterial blood gas (ABG) analysis. Definitive diagnosis ultimately requires scene investigation by a trained and suitably outfitted team. Determination of the exact nature of the gas is of limited clinical value but may have important public health implications. Since the presenting complaints offered by most exposed patients are nonspecific and protean (e.g., dizziness, syncope, and dyspnea), the differential diagnosis is extensive.

**Management and Disposition**

Management rarely requires specific therapy other than removal from exposure, supportive care, and possibly administration of supplemental oxygen. Neurologic injury or cardiorespiratory arrest should be managed with standard resuscitation protocols. Patients with manifestations of mild poisoning who recover after removal from the exposure can be observed briefly and discharged. Patients at risk for complications of hypoxia, such as those presenting with significant symptoms (e.g., coma) or with exacerbating medical conditions (e.g., cardiac disease), should be observed for the development or progression of posthypoxic complications.

---

**KEY CONCEPTS**

- Any gas can be an asphyxiant if it displaces sufficient oxygen from the breathable air.
- Appropriate therapy for asphyxiation includes removal from exposure, oxygen, and supportive care.

PULMONARY IRRITANTS

Perspective

The pulmonary irritant gases are a large group of agents that produce a common toxicologic syndrome when inhaled in moderate concentrations. Although many of these agents can be found in the home, significant poisoning from consumer products is uncommon because of restrictions designed to reduce their toxicity. However, catastrophes such as the 1984 release of methyl isocyanate in Bhopal, India, which resulted in more than 2000 fatalities and 250,000 injuries, remain as an environmental risk. On a different scale, industrialization has increased ambient levels of sulfur dioxide, ozone, and oxides of nitrogen. These irritant gases frequently exacerbate chronic pulmonary disease.

Principles of Disease

Irritant gases dissolve in the respiratory tract mucus and alter the air-lung interface by invoking an irritant or inflammatory response. When dissolved, most of the gases produce an acid or alkaline product, but several generate oxygen-derived free radicals that produce direct cellular toxicity (Fig. 157-1). Pulmonary irritants are grouped by their water solubility (see Table 157-1).

Clinical Features

Highly water-soluble gases have their greatest impact on the mucous membranes of the eyes and upper airway. Exposure results in immediate irritation, with lacrimation, nasal burning, and cough. Although their pungent odors and rapid symptom onset tend to limit significant exposure, massive or prolonged exposure can result in life-threatening laryngeal edema, laryngospasm, bronchospasm, or acute lung injury (ALI), formerly known as “noncardiogenic pulmonary edema.”4 Poorly watersoluble gases do not readily irritate the mucous membranes, and some have pleasant odors (e.g., phosgene’s odor is similar to that of hay). Since there are no immediate symptoms, prolonged breathing in the toxic environment allows the gas to reach the alveoli. Even moderate exposure causes irritation of

Figure 157-1. Sample reactions of pulmonary irritants reacting with water in the lung.
the lower airway, alveoli, and parenchyma and causes pulmonary endothelial injury after a 2- to 24-hour delay. Initial symptoms consistent with ALI may be mild, only to progress to overt respiratory failure and acute respiratory distress syndrome during the ensuing 24 to 36 hours.6

Gases with intermediate water solubility tend to produce clinical syndromes that are a composite of the other gases, depending on the extent of exposure. Massive exposure is most often associated with rapid onset of upper airway irritation and more moderate exposure with delayed onset of lower airway symptoms.6

Diagnostic Strategies and Differential Considerations

The evaluation of upper airway symptoms is usually done through physical examination but may require laryngoscopy. After exposure, swelling may occur rapidly or may be delayed, so a normal oropharyngeal or laryngeal evaluation may not exclude subsequent deterioration. Radiographic and laboratory studies have little role in the evaluation of upper airway symptoms.

Oxygenation and ventilation are assessed by serial chest auscultation and pulse oximetry, supplemented by chest radiography and ABGs in patients with cough, dyspnea, hypoxia, or abnormal findings on physical examination. No clinical tests can identify the specific irritant, and identification is not generally necessary for patient care, although knowing the causative agent may allow reduction of the observation period.

Bronchospasm, cough, chest tightness, and acute conjunctival irritation frequently follow allergen exposure, but the history generally suggests the diagnosis. ALI occurs after many physiologic insults, including trauma and sepsis, again highlighting the need for accurate history taking.

Management

Signs of upper airway dysfunction (e.g., hoarseness and stridor) mandate direct visualization of the larynx and immediate airway stabilization, if necessary. Given the potential rapidity of airway deterioration, early and frequent reassessment should be performed.

Bronchospasm generally responds to inhaled beta-adrenergic agonists; the role of ipratropium is not yet defined. Other than as a standard treatment for a comorbid condition, such as asthma, there is no clear indication for corticosteroids.7

Patients exposed to chlorine or hydrogen chloride gas receive symptomatic relief from nebulized 2% sodium bicarbonate solution.9 Because the inflammatory cascade is not altered, however, the component of lung injury mediated by free radicals probably continues and causes delayed deterioration. Patients receiving inhalational bicarbonate therapy require extensive discharge instructions for signs and symptoms of pulmonary irritation or admission to the hospital.

Diagnosis of ALI or acute respiratory distress syndrome indicates the need for aggressive supportive care, including manipulations of the patient’s airway pressures (e.g., continuous positive airway pressure and positive end-expiratory pressure). Exogenous surfactant and nitric oxide may have a beneficial role in toxin-induced acute respiratory distress syndrome, despite little support for its use in other forms of the syndrome.

Disposition

Patients exposed to highly water-soluble agents can be discharged if they are asymptomatic or improve with symptomatic therapy. After exposure to intermediate or poorly water-soluble agents, asymptomatic patients should be observed for increasing dyspnea for several hours before final disposition. Patients with substantial exposure to these agents or those in high-risk situations (e.g., underlying pulmonary disease, extremes of age, and poor follow-up) should be observed for 24 hours and may require hospitalization. All patients should be instructed to return if symptoms recur.

KEY CONCEPTS

- Highly water-soluble agents produce rapid irritation and predominantly upper respiratory tract symptoms such as bronchospasm.
- Poor water-soluble agents often produce delayed lower respiratory tract findings such as pulmonary edema.

SMOKE INHALATION

Perspective

Annually, 4000 people are injured or die in residential fires in the United States. Many of these casualties do not suffer serious cutaneous burns but, rather, die from smoke inhalation. This is a variant of irritant injury in which heated particles matter and adsorbed toxins injure normal mucosa, similar to other irritant gases. In addition, carbon monoxide and cyanide are systemic toxins often discussed with the smoke inhalation syndrome because of their common origin.

Principles of Disease

Even at temperatures between 350° C and 500° C, air has such a low heat capacity that it rarely produces lower airway damage. However, the greater heat capacities of steam (approximately 4000 times that of air) or heated soot suspended in air (i.e., smoke) can transfer heat and cause injury deep within the respiratory tract.

The nature of the fuel determines the composition of its smoke, and because fires involve variable fuels and burning conditions, the character of fire smoke is almost always undefined to the clinician. Irritant toxins produced by the fire are adsorbed onto carbonaceous particles that deposit in the airways. The irritant substances damage the mucosa through mechanisms similar to those of the irritant gases, including generation of acids and free radical formation.

Clinical Features

Most smoke-associated morbidity and mortality relate to respiratory tract damage. Thermal and irritant-induced laryngeal injury may produce cough or stridor, but these findings are often delayed. Soot and irritant toxins in the airways can produce initial cough, dyspnea, and bronchospasm. Subsequently, a cascade of airway inflammation results in acute lung injury and failure of pulmonary gas exchange. The time between smoke exposure and the onset of clinical symptomatology is highly variable and dependent on the degree and nature of the exposure. Singed nasal hairs and soot in the sputum suggest substantial exposure but are neither sufficiently sensitive nor specific to be practical.8

Carbon monoxide (CO) inhalation should be routinely considered in these patients. Patients who are exposed to filtered or distant smoke (e.g., in a different room) or to relatively smokeless combustion (e.g., engine exhaust) inhale predomi-
nantly CO, cyanide, and metabolic poisons and do not sustain smoke exposure.

**Diagnostic Strategies and Differential Considerations**

Early death is caused by asphyxia, airway compromise, or metabolic poisoning (e.g., CO). Airway patency should be evaluated early, optimally with fiberoptic laryngoscopy. If evidence of significant airway exposure is present, such as carbonaceous sputum or hoarse voice, the airway should be examined by direct or fiberoptic laryngoscopy. Simply observing the patient for deterioration can result in airway compromise requiring rapid and, by then, very difficult airway intervention. Signs of alveolar filling or hyperinflation for CO on pulmonary function testing, or abnormal distribution and clearance of radiolabeled gas on ventilation scans can help predict lower airway injury.

Metabolic acidosis, particularly when associated with a serum lactate level greater than 10 mmol/L, suggests concomitant cyanide poisoning. Oxygenation should be assessed by co-oximetry because ABG analysis and pulse oximetry may be inaccurate in CO-poisoned patients.

With the obvious exposure history, the differential diagnosis is limited. Although it is often unclear whether inhalational injuries are thermal or irritant, the differentiation is clinically irrelevant. CO and cyanide should be considered in every case.

**Management**

The acute management of victims of smoke inhalation is identical to that of other irritant inhalational injuries. Rapid assessment of the airway and early intubation, as indicated, are critical because deterioration may be precipitous. Inhaled beta-adrenergic agonists are widely used but without evidence supporting their benefit. Optimal supportive care and maintenance of adequate oxygenation (e.g., suctioning and pulmonary toilet) are the most important aspects of care. Bronchoscopy with bronchoalveolar lavage is frequently recommended to clear debris and toxins from the distal airways. Corticosteroids, whether inhaled or systemic, are not indicated and are potentially harmful in patients with cutaneous burns. Ibuprofen, antioxidants, exogenous surfactant, and high-frequency ventilation yield variably improved survival in experimental and clinical trials; none are generally considered as standard care. Antibiotics should be used only in patients with suspected infection.

**Disposition**

After the airway is examined and stabilized, patients with worrisome clinical findings (e.g., hoarseness and respiratory distress) and those with identifiers of substantial exposure (e.g., closed-space exposure and carbonaceous sputum) should be admitted to a critical care unit or transferred to a burn center. This decision will vary based on local resources, such as hospital capabilities or availability of a burn referral center.

---

**KEY CONCEPTS**

- Smoke inhalation injury is typically irritant in nature.
- Early visualization of the airway is essential. Early intubation prior to deterioration is critical if damage is present.
- Consider CO and cyanide in smoke inhalation.

---

**CYANIDE AND HYDROGEN SULFIDE**

**Perspective**

Hydrogen cyanide (prussic acid) is a gas with many commercial uses, particularly in synthetic fiber manufacture and fumigation. Hydrogen cyanide is occasionally noted to have the odor of bitter almonds. Cyanide in its salt form (e.g., sodium or potassium) is important in the metallurgic (e.g., jewelry) and photographic industries and is much safer to work with because of its low volatility. Cyanide salts do not have an odor under dry conditions. When cyanide salts are dissolved in water, hydrogen cyanide can leave the surface, particularly under acidic conditions. Cyanide is generated in vivo from precursors (cyanogens) such as amygdalin, found in apricot and other Prunus species pits, and from nitriles, a group of chemicals with many commercial uses.

Hydrogen sulfide poisoning most often occurs in petroleum refinery and sewage storage tank workers. Occasionally, well-intentioned would-be rescuers become victims, emphasizing the need for proper training and equipment. Hydrogen sulfide has a noxious odor similar to rotten eggs, which becomes noticeable with extremely high concentrations or prolonged exposure (olfactory fatigue).

**Principles of Disease**

Gaseous cyanide is rapidly absorbed after inhalation and is immediately distributed to the oxygen-utilizing body tissues. Inhibition of oxidative metabolism by binding to complex IV of the electron transport chain within mitochondria occurs within seconds. The poisoned tissue rapidly depletes its adenosine triphosphate reserves and ceases to function (Fig. 157-2). Cyanide has no evident effect on other oxygen-binding enzyme systems, most notably hemoglobin. This is probably explained by the oxidation state of its iron moiety; cyanide binds only to oxidized iron (Fe³⁺), whereas deoxyhemoglobin contains reduced iron (Fe²⁺).

Hydrogen sulfide exerts its toxic effects both as a pulmonary irritant and as a cellular poison. Its deadly metabolic effects are produced by a mechanism identical to that for cyanide poisoning. However, hydrogen sulfide’s spontaneous dissociation from the mitochondria is rapid, allowing many patients to survive after brief exposure.

**Clinical Features**

Tissue hypoxia occurs within minutes, with the exact speed dependent on the route and nature of the exposure. Dysfunction of the heart and the central nervous system—the organ systems most sensitive to hypoxia—is characteristic of cyanide poisoning, manifesting as coma, seizures, dysrhythmias, and cardiovascular collapse. Metabolic acidosis develops due to diffuse cellular dysfunction and is associated with an elevated serum lactate. Cyanosis is not characteristic but can be present in profoundly poisoned patients. Given the extreme toxicity of cyanide, mild acute poisoning is uncommon. Patients with acute hydrogen sulfide poisoning have similar clinical manifestations, although many are recovering by the time of arrival in the emergency department.

Because cyanide and hydrogen sulfide prevent tissue extraction of oxygen from the blood, the oxygen content of venous blood remains high, approaching that of arterial blood. Clinically, this may appear as the “arterialization,” or brightening, of venous blood to resemble arterial blood. A comparison of the measured venous (ideally but impractically mixed venous) and arterial oxygen contents may assist in the diagnosis of
The elevated carboxyhemoglobin concentration in a fire victim is highly predictive of cyanide poisoning. An are usually present. A lactate level greater than 10 mmol/L in a fire victim is highly predictive of cyanide poisoning. Pulse oximetry and ABG analysis are accurate in cases of situations of exposure and a corroborative physical examination. Obtaining the results of a serum cyanide level generally requires too much time for these to be of use in the emergency department, but these results can be useful for confirmation and documentation purposes. Technology exists for immediate cyanide determination but is not widely available. Rapid tests for hydrogen sulfide are not available.

In practice, the diagnosis must be based on the circumstances of exposure and a corroborative physical examination. Pulse oximetry and ABG analysis are accurate in cases of isolated cyanide or hydrogen sulfide poisoning. An increased anion gap metabolic acidosis and elevated serum lactate level are usually present. A lactate level greater than 10 mmol/L in a fire victim is highly predictive of cyanide poisoning. An elevated carboxyhemoglobin concentration in a fire victim may suggest concomitant cyanide poisoning but may take too long to obtain and may falsely exclude patients exposed to combustion products of substances that generate only cyanide (e.g., certain plastics).

Rapid cardiovascular collapse, ventricular dysrhythmias, and seizures are typical and, in a fire victim, should suggest cyanide poisoning. However, each of these findings is also consistent with severe CO poisoning. This differentiation may be important given the implication of the treatment for cyanide poisoning.

**Diagnostic Strategies and Differential Considerations**

Obtaining the results of a serum cyanide level generally requires too much time for these to be of use in the emergency department, but these results can be useful for confirmation and documentation purposes. Technology exists for immediate cyanide determination but is not widely available. Rapid tests for hydrogen sulfide are not available.

In practice, the diagnosis must be based on the circumstances of exposure and a corroborative physical examination. Pulse oximetry and ABG analysis are accurate in cases of isolated cyanide or hydrogen sulfide poisoning. An increased anion gap metabolic acidosis and elevated serum lactate level are usually present. A lactate level greater than 10 mmol/L in a fire victim is highly predictive of cyanide poisoning. Rapid cardiovascular collapse, ventricular dysrhythmias, and seizures are typical and, in a fire victim, should suggest cyanide poisoning. However, each of these findings is also consistent with severe CO poisoning. This differentiation may be important given the implication of the treatment for cyanide poisoning.

**Management**

Patients exposed to cellular poisons, including hydrogen cyanide and hydrogen sulfide, require individualized and specific therapy. The diagnosis can usually not be confirmed, and therapy is almost always empirical but should not be delayed in patients with suspected acute cyanide poisoning. In uncertain situations, antidotal therapy should be administered immediately.

**Hydrogen Cyanide**

The accepted goal of therapy is to reanimate the cytochrome oxidase system by providing an alternative binding site for the cyanide ion. There are two types of antidotal therapy for
cyanide. The cyanide antidote kit produces a high-affinity source of ferric ions (Fe$^{3+}$) for cyanide to bind. The kit has three components, and although the best results are likely attained when the entire kit is used, this may be impractical or dangerous, particularly for nonhospital providers. Because animal models and clinical evidence in humans demonstrate that sodium thiosulfate alone (the “third” part of the kit), in combination with oxygen and sodium bicarbonate, offers substantial protection, this should be the initial therapy administered by paramedics and during mass poisoning events. At all times, appropriate resuscitation measures including high flow oxygen and intravenous fluids should be provided.

Methemoglobin (MetHb) formation is the goal of the first two parts of the kit. Inhaled amyl nitrite or intravenous sodium nitrite are both effective, but the former should only be administered in patients for whom intravenous access cannot be obtained. Caution should be taken to minimize the provider’s exposure to the volatile amyl nitrite because dizziness, hypotension, or syncope may occur. The dose of sodium nitrite for a previously healthy adult is 300 mg (10 mL of a 3% solution) given over 2 to 4 minutes, and dosing instructions for anemic patients and children are supplied with the kit. Sodium nitrite is a vasodilator, and hypotension may complicate a rapid infusion. Cyanide has a high affinity for MetHb and readily leaves cytochrome oxidase to form cyanomethemoglobin. Both free serum cyanide and cyanomethemoglobin are converted by sulfur transferase (rhodanese) to thiocyanate, which is renally eliminated. Since the rate of rhodanese function increases with the availability of sulfur donor, the third part of the antidote kit is the sulfur-containing compound sodium thiosulfate. The adult dose is 12.5 g intravenously (IV), which is provided as 50 mL of a 25% solution (1.65 mL/kg of 25% sodium thiosulfate in children). Generally, few, if any, adverse effects are associated with proper doses. The nitrite components of the cyanide antidote kit should be avoided in fire victims with possible simultaneous CO and cyanide poisoning. Since both CO and methemoglobin reduce oxygen delivery to the tissues, complications may arise. The use of the thiosulfate component alone in this subset of patients is recommended.

Hydroxocobalamin is a newer antidotal therapy that takes advantage of the high affinity of cobalt for cyanide. Upon binding cyanide, cyanocobalamin, or vitamin B$_{12}$, is formed. This antidote has been used for years in Europe and is rapidly gaining acceptance in the United States, including for use in mass poisonings. However, although it is approved by the Food and Drug Administration for treatment of known or suspected cyanide poisoning, its specific clinical role has not been fully explored. The initial dose is 5 g IV over 15 minutes for adults and 70 mg/kg IV in children, up to an adult dose. The known adverse effects are mild and include slight hypertension in those not cyanide poisoned and a bright red discoloration of the patient’s skin. Due to the red drug's color, interference with certain spectrophotometric laboratory tests, including carboxyhemoglobin and possibly serum lactate, may prove consequential. Blood samples should be obtained prior to the administration of the first dose of hydroxocobalamin. There are insufficient clinical data to support the use of one cyanide antidote over the other. However, because hydroxocobalamin does not alter oxygen delivery, it should be safer than the nitrite-based antidote kit empirically in a fire victim. Direct comparison to thiosulfate alone has not been, and likely will never be, performed.

Hyperbaric oxygen therapy has been advocated but is of no proven benefit and is not routinely indicated. In selected cases, when immediately available, its apparent value may lie in its ability to superoxygenate plasma and tissues, thus permitting higher levels of methemoglobinemia, particularly when CO poisoning is also present.

**Hydrogen Sulfide**

Since the bond between hydrogen sulfide and cytochrome oxidase is rapidly reversible, removal from exposure and standard resuscitative techniques are usually sufficient to reverse hydrogen sulfide toxicity. Use of the nitrite portion of the cyanide antidote kit is suggested to create MetHb for patients with severe or prolonged toxicity. Sodium thiosulfate is unnecessary because hydrogen sulfide is not detoxified by rhodanese. There is no role for hyperbaric oxygen therapy in cases of hydrogen sulfide toxicity.

**Disposition**

All patients with symptomatic cyanide or hydrogen sulfide poisoning should be admitted to a critical care unit and observed for complications of tissue hypoxia. All patients should be followed for delayed neuropsychiatric symptoms.

---

**KEY CONCEPTS**

- An antidote for cyanide poisoning must be administered early.
- The sodium thiosulfate portion of the cyanide antidote kit is safe for empirical administration in any case in which cyanide poisoning is considered possible.
- Hydroxocobalamin is a safe and effective antidote, although its exact role in empirical therapy of fire victims is unclear.
- Patients with hydrogen sulfide poisoning generally respond to removal from exposure and ventilatory support.

---

**CARBON MONOXIDE**

**Perspective**

Carbon monoxide is the most common cause of acute poisoning death in developed nations and the most common cause of fire-related death. CO is generated through incomplete combustion of virtually all carbon-containing products. Structure fires (e.g., wood), clogged vents for home heating units (e.g., methane), and use of gasoline-powered generators indoors are examples of the myriad means through which patients are poisoned by CO. Appropriate public health authorities (e.g., fire department and Department of Health officials) should be informed immediately about any potential public health risks that are identified during the care of a CO-exposed patient.

**Principles of Disease**

Carbon monoxide interacts with deoxyhemoglobin to form carboxyhemoglobin (COHb), which cannot carry oxygen. Hemoglobin binds CO tightly and forms a complex that is only slowly reversible. This allows the exposed individual to accumulate CO, even with exposure to low ambient concentrations. Although hemoglobin binding is the classically described mechanism of CO poisoning, it is relevant only to patients who are profoundly CO poisoned because a simple reduction in oxygen-carrying capacity due, for example, to anemia would not be expected to result in similar symptoms. However,
relevant to the management of pregnant patients, the fetus is always relatively hypoxic compared to the mother, and fetal hemoglobin binds CO better than adult hemoglobin. In muscle, CO binds myoglobin, preventing its normal function, and this likely explains the development of atrophic rhabdomyolysis.

Most important, CO affects cellular oxygen utilization at the tissue level. CO, similarly to cyanide, inhibits the final cytochrome complex involved in mitochondrial oxidative phosphorylation. This results in a switch to anaerobic metabolism and, ultimately, in cellular death.

Delayed-onset neurologic complications may be a manifestation of the hypoxic insult, although reperfusion injury and lipid peroxidation related to platelet-induced nitric oxide release may play a significant role. By altering the platelet-associated nitric oxide cycle, the microvascular endothelium of the central nervous system undergoes free radical-mediated injury, resulting in localized inflammation and dysfunction. Animal models and human reports suggest that loss of consciousness during CO exposure may be necessary, and is certainly a risk factor, for the development of delayed neurologic sequelae.

Clinical Features

Severe CO toxicity and cyanide poisoning have identical clinical presentations of asphyxia: altered mental status, including coma and seizures; extremely abnormal vital signs, including hypotension and cardiac arrest; and metabolic acidosis. Unlike cyanide poisoning, however, mild CO poisoning occurs frequently, with headache, nausea, vomiting, dizziness, myalgia, or confusion as common presenting complaints. The neurologic assessment in these patients may yield normal findings or may demonstrate focal findings or subtle perceptual abnormalities. The often-touted cherry-red skin color in patients with cyanide or CO poisoning is a postmortem finding and is not noted in living patients.

Delayed neurologic sequelae are a well-documented phenomenon after CO exposure, although the frequency varies from 12 to 50%, depending on the definition and the sensitivity of the test used for their detection. Patients develop a variety of neurologic abnormalities after an asymptomatic period ranging from 2 to 40 days. The delayed neurologic effects can be divided into those with readily identifiable neurologic syndromes (e.g., focal deficits and seizures) and those with primarily psychiatric or cognitive findings (e.g., apathy and memory deficits). Although the latter form of delayed neurologic sequelae requires formal neuropsychiatric testing for detection, the impact of these abnormalities on the patient’s daily function may be significant. Risk factors that predict the development of delayed neurologic sequelae include age and loss of consciousness. Since the majority of CO poisoned patients reaching the emergency department survive, prevention of delayed neurologic and neuropsychiatric sequelae is the predominant goal of therapy.

Diagnostic Strategies and Differential Considerations

Suspicion of CO poisoning relies on the history and physical examination findings. Co-oximetry, an inexpensive and readily available spectrophotometric laboratory method that can distinguish between the normal hemoglobins and COHb (and MetHb), confirms exposure to CO. Other laboratory tests only exclude other diagnoses. Severity of poisoning may not correlate with COHb levels; prolonged exposure to low levels can result in fatality with low COHb, but a brief, high-concentra-

tion exposure can produce a high COHb level with minimal symptoms.

The ABG measurement cannot be used as a diagnostic test for CO poisoning other than to identify the presence of a metabolic acidosis and a normal partial pressure of oxygen (P02). CO does not affect the amount of oxygen dissolved in the blood. Because the P02, a measure of dissolved oxygen, is normal in patients with CO poisoning, the calculated oxygen saturation will be normal even in the presence of substantial CO poisoning. Most pulse oximeters are inadequate for the detection of CO poisoning because COHb is essentially misinterpreted as oxyhemoglobin. Newer pulse oximeters (pulse co-oximeters) are capable of detecting COHb, as well as methemoglobinemia, but are not yet widely available.

Mild to moderate CO poisoning is a difficult diagnosis to establish clinically, and patients are easily misdiagnosed as having a benign headache syndrome or viral illness. CO poisoning should be suspected in every patient with persistent or recurrent headache, especially if a group of people have similar symptoms or if the headache improves soon after the person leaves an exposure site.

Patients with severe CO poisoning may present with coma or cardiovascular collapse, both of which have a broad toxicologic, metabolic, infectious, medical, and traumatic differential diagnosis. Many diagnoses are excluded by the medical history, physical examination, or standard laboratory testing. Given the relatively protean manifestations of CO poisoning, when seriously considered, it should be excluded by co-oximetry of an arterial or venous blood sample or pulse co-oximetry. Misdiagnosis can be catastrophic, particularly if the patient returns to the poisoned environment.

Management

Treatment begins with oxygen therapy, which serves two purposes. First, the half-life of COHb is inversely related to the Po2; it can be reduced from approximately 5 hours on room air to 1 hour by providing supplemental 100% oxygen. Hyperbaric oxygen therapy (HBOT) further reduces the half-life to approximately 30 minutes. Altering the kinetics of COHb is only applicable to patients with extremely elevated COHb levels (e.g., >50%). Even then, few patients can be treated rapidly enough that enhanced CO clearance by HBOT would be lifesaving. Second, a sufficient Po2 can be achieved with HBOT to sustain life in the absence of adequately functioning hemoglobin, but this is also relevant only to situations in which the COHb is extremely elevated. Thus, the primary indication for hyperbaric oxygen is to prevent delayed neurologic sequelae.

The controversy regarding the clinical utility of HBOT is largely related to the fact that a benefit is not identified immediately (as with life and death) but, rather, requires close follow-up and sophisticated testing. Although the literature base on which to make decisions is poor, several evidence-based reviews have suggested a limited role for HBOT, although this conclusion is disputed. HBOT is associated with a reduction in the rate of delayed neurologic sequelae from approximately 12% without HBOT to less than 1%. When HBOT administration is delayed more than 6 hours after exposure, its efficacy appears to decrease, suggesting the need for rapid decision making. Similarly, evidence suggests that HBOT positively affects the development of the neuropsychiatric delayed neurologic sequelae after CO poisoning. A randomized, double-blind study found that HBOT was superior to normobaric oxygen therapy (NBOT) at reducing the incidence of neuropsychiatric delayed neurologic sequelae at both 6 weeks and 1 year postpoisoning.
However, it is not universally accepted that HBOT is useful in preventing the development of neuropsychiatric delayed neurologic sequelae. An earlier Australian study that compared HBOT to NBOT suggested that there was no benefit of HBOT on the development of neuropsychiatric delayed neurologic sequelae. In this study, however, the majority of patients were suicidal and presumably depressed, a condition that interferes with performance on the neuropsychiatric testing needed to differentiate the two groups of patients. In addition to other methodologic flaws in the study (e.g., mean delay to hyperbaric oxygen of more than 6 hours, atypical hyperbaric regimen, unusual randomization protocol, and limited neuropsychiatric testing), the alternative to HBOT suggested by this study is continuous 100% NBOT for 3 or 6 days, which is unlikely to be accepted by both patients and the medical community.

Given the implications of poor tissue oxygenation due to the presence of COHb, many practitioners suggest that any patient with a neurologic abnormality or cardiovascular instability (e.g., syncope, altered mental status, myocardial ischemia, and dysrhythmias) is a candidate for HBOT. This consideration should be relatively independent of the patient’s COHb level, which correlates only weakly with toxicity. Patients with prolonged low-level exposure develop a “soaking” phenomenon, in which extremely high tissue concentrations of CO occur without the patient developing very high COHb levels.

In addition to using HBOT in those patients with obvious signs of tissue hypoxia, some institutions have set an arbitrary conservative COHb level of 25% at which asymptomatic or minimally symptomatic patients will be referred for HBOT. This seems appropriate, although some institutions use COHb levels of 40%, and others refrain from specifying a number. Special consideration is given for pregnancy because of the relative hypoxia of the fetus. Because fetal CO poisoning is associated with dysfunction and death, and HBOT appears to be safe in pregnancy, many institutions have lowered the standard for initiating hyperbaric oxygen therapy in a pregnant patient to a COHb level of 15%.

Further study is still needed to define the optimal duration, pressure, and frequency as well as the cost-benefit and risk-benefit relationships of hyperbaric oxygen therapy. At this time, discussion with a regional HBOT center or poison control center is advisable. Patients with elevated COHb levels who do not require HBOT should be treated with normobaric oxygen therapy delivered by a tight-fitting non-rebreather face mask, at least until the symptoms resolve and the COHb levels fall. The total duration of such therapy is undefined, and although 3 days was suggested in one study, most mildly CO-poisoned patients probably require no more than 6 hours of therapy.

Simultaneous Carbon Monoxide and Cyanide Poisoning (Fire Victim)

Concurrent toxicity from CO and cyanide is widely reported and a major factor in the mortality associated with exposure to fire smoke. Smoke inhalation victims who present with coma and metabolic acidosis can have severe CO poisoning, cyanide poisoning, or both. Nitrite-induced methemoglobinemia, which further reduces the tissue oxygen delivery, may be detrimental to patients with elevated COHb levels.

Sodium thiosulfate, administered without nitrites, or hydroxocobalamin should be given to all smoke inhalation victims with coma, hypotension, acidosis, or cardiovascular collapse in whom cyanide poisoning cannot be rapidly excluded. If the COHb level is known to be low and the patient has persistent acidosis or hemodynamic instability, the complete cyanide antidote kit, including the nitrites, can be administered. Patients with high COHb levels undergoing therapy in a hyperbaric oxygen chamber can receive nitrite therapy while pressurized with little concern of decreasing the oxygen-carrying capacity. Alternatively, hydroxocobalamin, with or without sodium thiosulfate, can be administered in either of these last two situations.

Disposition

The decision to transfer a patient to a hyperbaric facility must consider the time delay to therapy, patient issues (e.g., burns and age), and potential transport-related complications. At a minimum, prolonged NBOT should be administered, although the benefit of this remains undefined. Admission decisions should be based on the patient’s clinical condition. All patients exposed to CO require close follow-up to evaluate for delayed neurologic sequelae.

### KEY CONCEPTS
- Carbon monoxide poisoning is common and has important public health implications.
- Carbon monoxide poisoning can be obscure and should be corroborated with co-oximetry.
- Because the role of hyperbaric oxygen therapy in CO poisoning is controversial, consultation with a hyperbaric oxygen facility or poison control system may be helpful in cases of significant toxicity.

Chapter 158  Lithium
Oliver Hung

**PERSPECTIVE**

Lithium has been used as a medicinal agent since the mid-1800s, when lithium salts were popularized as a treatment for gout (lithium carbonate and lithium citrate), a sedative for manic patients (lithium bromide), and as a treatment for epilepsy (lithium bromide). In 1929, the soft drink “7 Up,” whose original name was “Bib-Label Lithiated Lemon-Lime Soda,” included lithium citrate as an ingredient (until 1950) and was marketed as a patent medicine to cure hangovers. In the late 1940s, lithium chloride was used as a salt substitute for patients requiring low-salt diets. However, in 1949, the Food and Drug Administration (FDA) banned the use of lithium because of several patient deaths attributed to lithium toxicity. Ironically, in the same year, a study by the Australian psychiatrist John Cade convincingly demonstrated the efficacy of lithium for the treatment of bipolar disorder. Use of lithium was prohibited in the United States until 1970, when the FDA reversed the ban on lithium and approved its use as a treatment for bipolar disorder. Despite the introduction of newer and safer medications, lithium is established as the most effective long-term treatment to prevent recurrences of mania and bipolar disorder. Lithium treatment also appears to substantially decrease the risk of suicide and suicide attempts. According to U.S. poison center data, in 2006 there were 5674 reported lithium exposures with 149 major outcomes (life-threatening or significant residual disability) and 7 deaths.

**PRINCIPLES OF DISEASE**

The precise mechanism of action of lithium as a mood-stabilizing agent is not fully understood. Lithium increases serotonin release and serotonin receptor sensitivity, and it also inhibits norepinephrine and dopamine release from nerve terminals. Postulated mechanisms have begun to focus on cellular pathways, including intracellular signaling, neuronal plasticity/neurogenesis, and gene expression. These mechanisms include the inositol depletion hypothesis, glycogen synthase kinase-3 inhibition, and the arachidonic acid cascade hypothesis. In the inositol depletion hypothesis, lithium inhibits inositol monophosphatase, which depletes brain cell myoinositol and dampens phosphoinositide signaling. Lithium’s neuroprotective properties are attributed to its ability to inhibit glycogen synthase kinase-3. Finally, in the arachidonic cascade hypothesis, lithium reduces the amount of arachidonic acid recycled in brain cells. Bipolar disorder is thought to result from a hyperactive arachidonic acid cellular signaling cascade.

Immediate-release lithium is rapidly absorbed from the gastrointestinal tract. Peak plasma concentrations occur 0.5 to 3 hours after a single oral dose, with complete absorption within 8 hours. Sustained-release lithium preparations exhibit variable absorption, with a delayed peak of 6 to 12 hours. Ingestion of a single 300-mg lithium carbonate tablet increases the serum lithium level by approximately 0.1 mEq/L. After absorption, lithium distribution follows an open two-compartment model. Lithium is initially distributed in the extracellular fluid and then gradually redistributes in various tissue compartments (preferentially the brain, kidney, thyroid, and bone). Brain lithium distribution may take up to 24 hours following absorption. Approximately 95% of a single dose of lithium is excreted by the kidney. Lithium is freely filtered by the glomerulus, with 80% of filtered lithium reabsorbed by the proximal renal tubule. Lithium renal elimination is increased by factors that decrease glomerular filtration rate (e.g., dehydration) or sodium concentration (e.g., hyponatremia). Medications such as non-steroidal anti-inflammatory drugs, diuretics, and angiotensin-converting enzyme inhibitors may increase lithium levels by interfering with renal lithium elimination.

Chronic lithium therapy is also associated with the development of nephrogenic diabetes insipidus, resulting in hyponatremia and dehydration, which may increase lithium levels. Fluid resuscitation and lithium cessation are usually sufficient in permanently reversing the effects of diabetes insipidus. Lithium also inhibits the synthesis and release of thyroid hormone. Hypothyroidism is a rare complication (5% of all patients) of chronic lithium therapy. Finally, lithium causes a temporary leukocytosis and was once investigated as a potential treatment for chemotherapy-induced neutropenia.

**CLINICAL FEATURES**

Clinical manifestations of lithium poisoning can be classified based on whether the poisoning is due to acute toxicity, chronic toxicity, or acute-on-chronic toxicity.

Acute toxicity represents an overdose of lithium in a patient without any lithium body stores. Gastrointestinal symptoms such as nausea, vomiting, and diarrhea are the earliest and most common presentation of toxicity. Lithium also causes electrocardiographic effects, including bradycardia, T wave flattening or inversion, and QT prolongation. Fortunately,
significant cardiac dysrhythmias following lithium poisoning are rare. Neurotoxicity is delayed because of the time required for lithium to distribute to the brain.

In chronic toxicity, the patient, who takes lithium regularly and has significant lithium body stores, develops toxicity because of increased absorption or decreased lithium renal elimination (e.g., dehydration, drug interactions, and renal insufficiency). Neurotoxicity is the predominant presentation. Mild toxicity may manifest as a worsening tremor. Progressively more severe signs of neurotoxicity include drowsiness, hyper-reflexia, confusion, clonus, coma, seizures, and extrapyramidal signs. The syndrome of irreversible lithium-effectuated neurotoxicity (SILENT) has been described and is defined as persistent neurologic dysfunction attributed to lithium toxicity persisting 2 months after lithium cessation.6

Typical SILENT presentations include cerebellar dysfunction, persistent extrapyramidal syndromes, brainstem dysfunction, and dementia. The presence of fever is also considered a poor prognostic sign and possible precipitant of SILENT.6

Finally, in acute-on-chronic toxicity, a patient who is already taking lithium ingests an additional quantity of lithium in excess of the prescribed dosage. The clinical presentation is signs and symptoms of both acute and chronic toxicity, including gastrointestinal and neurologic symptoms.

Lithium use has also been implicated in the development of both neuroleptic malignant syndrome and serotonin syndrome. Serotonin syndrome usually results from the combination of serotonergic agents. Consequently, lithium should not be used in conjunction with serotonin agonists (e.g., monoamine oxidase inhibitor, selective serotonin reuptake inhibitors, dextromethorphan, buspirone, and meperidine). Lithium use is also considered a risk factor for neuroleptic malignant syndrome. The signs and symptoms of neuroleptic malignant syndrome, serotonin syndrome, and lithium toxicity are similar, with considerable overlap of symptoms (fever and neurologic deterioration). Fortunately, the initial treatment of lithium toxicity, serotonin syndrome, and neuroleptic malignant syndrome is the same and includes supportive care and discontinuation of the involved medication(s).

- **DIAGNOSTIC STRATEGIES**

Since the signs and symptoms of lithium toxicity are nonspecific and are often delayed following acute overdose, a serum lithium level should be obtained in any patient suspected of acute or chronic lithium poisoning. Obtaining serum electrolytes may be helpful in patient management. Increased serum sodium may indicate lithium-induced nephrogenic diabetes insipidus, whereas the serum creatinine level may help determine whether extracorporeal removal is required. Thyroid functions should also be obtained if clinical thyroid disease is suspected. Finally, obtaining an electrocardiogram and a serum acetaminophen level should be considered for acute, intentional ingestions to evaluate for the presence of co-ingestants.

- **DIFFERENTIAL DIAGNOSIS**

The differential diagnosis for lithium poisoning is extremely varied because of its nonspecific signs and symptoms. Consideration for alternate diagnosis can be based on whether the clinical presentation represents acute versus chronic lithium poisoning. Acute lithium poisoning typically presents with initial, prominent gastrointestinal symptoms that are similar to those of other drug overdoses. These include other metal salts (e.g., iron, arsenic, or mercury), salicylates, cardioactive steroids (e.g., digoxin), and theophylline. Chronic lithium poisoning, with its predominant neurologic symptoms, should raise concern for other neurologic conditions or central nervous system toxins, including central nervous system depressants, drugs that cause seizures, hypoglycemic agents, carbon monoxide, neuroleptic malignant syndrome, and serotonin syndrome.

- **MANAGEMENT**

There is no antidote for lithium poisoning; consequently, the management of lithium toxicity includes selected gastrointestinal decontamination (for acute overdose only), techniques to increase the elimination of lithium (renal and extracorporeal) from the body, and supportive care.

- **Gastrointestinal Decontamination**

Both oral activated charcoal and gastric lavage are ineffective in the management of lithium poisoning. Lithium is poorly absorbed by activated charcoal.7 Gastric lavage is ineffective for several reasons. The immediate-release lithium preparations are usually absorbed from the gastrointestinal tract too quickly for lavage or whole bowel irrigation to be effective. In addition, lithium-induced emesis would be expected to occur very quickly following an ingestion of immediate-release lithium, thereby limiting its own gastrointestinal absorption and making any attempt at gastric lavage potentially hazardous. Finally, sustained-release lithium tablets are too large to fit through an orogastric tube.

Whole-bowel irrigation with polyethylene glycol is the recommended gastrointestinal decontamination treatment for any overdose of sustained-release lithium preparation. It is the only form of decontamination that has demonstrated any efficacy in safely eliminating lithium in humans.8 The recommended rate of administration is 2 L/hr in adults and 500 mL/hr in children via gastric tube until the rectal effluent is clear (4–6 hours).

Sodium polystyrene sulfonate (Kayexalate), a cationic exchange resin used to treat hyperkalemia, has been investigated as a gastrointestinal decontamination method for lithium poisoning. In animal models and in two human case reports (one volunteer and one overdose patient), administration of oral sodium polystyrene sulfonate (30 g every 6 hours for five doses) has been demonstrated to be effective in decreasing serum lithium levels.7,9 However, it also significantly lowers serum potassium concentrations.10,11 Because of limited patient experience and concerns about life-threatening hypokalemia, sodium polystyrene sulfonate is not recommended.

- **Techniques to Increase Elimination**

Lithium can be removed by increasing renal elimination as well as by extracorporeal methods.

Fluid resuscitation with sodium chloride (normal saline) to correct hyponatremia and dehydration is the recommended method to maximize renal lithium elimination. Unless there are contraindications to aggressive volume expansion (e.g., renal insufficiency, congestive heart failure), administration of intravenous normal saline at a twice maintenance rate is recommended. Forced diuresis is not recommended because of the risk of causing hypernatremia and because of its variability in consistently increasing renal lithium elimination. Urinary alkalization by intravenous sodium bicarbonate is also not recommended because it does not significantly increase renal lithium elimination compared with volume expansion by sodium chloride (normal saline) and because of the additional risk of hypokalemia and alkaluria.
The most effective technique to eliminate lithium from the body is hemodialysis. Endogenous lithium renal clearance is approximately 15 to 20 mL/min, whereas hemodialysis lithium clearance is approximately 100 mL/min. Although hemodialysis substantially increases lithium elimination, its ability to decrease mortality or treat/prevent the syndrome of irreversible lithium-effectuated neurotoxicity has never been demonstrated. Consequently, there is no evidence-based consensus to define the indications for hemodialysis for lithium poisoning. Hemodialysis is primarily used for clinical deterioration (e.g., seizures and decreased level of consciousness), inadequate endogenous lithium clearance (e.g., renal insufficiency), or inability to enhance renal elimination through volume expansion (e.g., congestive heart failure, cirrhosis, pancreatitis, and sepsis). Although it may not correlate directly with toxicity, hemodialysis is recommended for a serum lithium level greater than 4.0 mEq/L for acute toxicity and greater than 2.5 mEq/L for chronic toxicity. Continuous renal replacement therapies (e.g., continuous venovenous hemodialysis) have also been successfully utilized to treat lithium-poisoned patients. Although their clearance rates are inferior to hemodialysis, they can be used in place of hemodialysis in hemodynamically unstable patient as well as in conjunction with hemodialysis in stable patients.

Because of the two-compartment model of lithium distribution in the body, serial lithium levels need to be monitored for increases after treatment due to redistribution from intracellular stores. In chronic lithium toxicity, rising lithium levels occur following hemodialysis, necessitating multiple hemodialysis treatments.

**DISPOSITION**

Hospital admission should be considered for any patient with suspected lithium poisoning with abnormal neurologic signs (e.g., hyper-reflexia, clonus, altered sensorium, or seizure) or any asymptomatic patient after acute overdose with increasing lithium levels. In addition, hospitalization at a center with emergency dialysis capability is preferable.

---

**KEY CONCEPTS**

- Lithium toxicity presents with nonspecific signs and symptoms.
- Consider lithium poisoning in any patient who is taking lithium and presents with an altered sensorium.
- Medications that impair renal function or environmental factors that lead to dehydration increase the risk of lithium toxicity.
- Early decontamination with whole-bowel irrigation and vigorous volume replacement are important in managing acute lithium toxicity.
- Consider hemodialysis in patients with severe signs and symptoms of neurotoxicity, inadequate renal function or inability to tolerate volume expansion (e.g., renal insufficiency and congestive heart failure), or a serum lithium level greater than 4.0 mEq/L in acute poisoning or greater than 2.5 mEq/L in chronic poisoning.
- Lithium has numerous drug interactions that may lead to adverse effects, including increased risk for lithium toxicity, increased lithium toxic effects, neuroleptic malignant syndrome, and serotonin syndrome.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
The first antipsychotic, chlorpromazine, was used for the treatment of psychosis in France in 1951 and in the United States in 1954. Antipsychotic use has expanded significantly since then. The term neuroleptic, historically synonymous with antipsychotic medication due to the high degree of sedation produced by earlier drugs, is no longer appropriate because newer agents cause little sedation. The term antipsychotic is now preferred. In 2006, U.S. poison control centers reported more than 4500 exposures to phenothiazines and 41,000 exposures to atypical antipsychotics, resulting in 1 and 11 deaths, respectively.

Antipsychotic medications are used to treat agitation and psychosis caused by schizophrenia, mania, acute idiopathic psychosis, alcohol withdrawal hallucinosis, and Alzheimer’s disease. The antipsychotic medications are often divided into three broad categories based on their receptor profiles, clinical effects, and adverse effects (Table 159-1). All antipsychotic medications effectively treat the positive symptoms of psychotic disorders; they reduce hallucinations, control agitation, and aid in restructuring disordered thinking. In general, the low-potency neuroleptics are the most sedating at usual doses. Movement disorders, including extrapyramidal symptoms (EPS) and tardive dyskinesia (TD), are significant problems with both low-potency and high-potency neuroleptics. In addition to producing less sedation and fewer movement disorders, the atypical antipsychotic agents assist with the negative symptoms of psychotic disorders, such as flat affect, avolition, social withdrawal, and impoverished thought and speech. Although neuroleptic malignant syndrome (NMS) has occurred with all agents, it occurs least with the atypical antipsychotics.

Extrapyramidal syndromes can be divided into two groups based on the time of onset after initiating drug therapy. The acute EPSs include dystonia, akathisia, and parkinsonism. These adverse effects are caused by blockade of nigrostriatal D₂ receptors and reduced by blocking muscarinic receptors. The propensity for antipsychotics to produce EPSs is inversely related to the agents’ muscarinic receptor antagonism. The delayed-onset syndromes, including TD and tardive dyskinesia, develop after prolonged use of antipsychotic medications thought to occur from chronic dopamine receptor blockade in the nigrostriatal area leading to D₂ receptor upregulation and hypersensitivity to dopamine. The pathophysiology of NMS, an idiosyncratic reaction to antipsychotic medication, is unknown, but it is thought to be from neuroregulatory dysfunction secondary to D₂ receptor blockade in the nigrostriatum and hypothalamus, leading to rigidity and hyperthermia, respectively. There is no apparent association with ryanodine receptor (RYR) gene mutations, which are associated with malignant hyperthermia, in NMS patients.
Most antipsychotic medications produce cardiovascular side effects. The most common side effect is orthostatic hypotension with reflexive tachycardia due to alpha-adrenergic blockade. Many agents cause conduction delays, predominantly QT prolongation. Blockade of the delayed inward rectifier potassium current prolongs repolarization during the cardiac action potential and potentially causes torsades de pointes (TDP).12,13 The degree of prolongation varies between antipsychotic agents, increasing with dose and with concomitant use of other drugs known to prolong the QT interval.14,15 The phenothiazines, particularly thioridazine and mesoridazine, have the greatest risk of cardiac toxicity. QT prolongation has also been reported with the butyrophenones, haloperidol and droperidol.12,14,16-18 The atypical antipsychotics produce less cardio-toxicity than the traditional agents, although most potentially cause repolarization abnormalities in therapeutic doses and overdose.5,14,19-21 Ultimately, a correlation between QT prolongation and the occurrence of dysrhythmias or TDP has not been established.4 Antipsychotics are associated with an increased risk of sudden death, particularly in patients with heart disease. However, psychotic disorders themselves are associated with an increased risk of sudden death.

Clozapine produces agranulocytosis in 1 or 2% of treated patients2; however, this has been reduced to 0.4% after strict adherence to labeling requirements.23 Although the mechanism of agranulocytosis is unknown, research supports an immunogenic cause.24 Seizure rarely occurs with antipsychotic drugs, but clozapine has the highest seizure incidence. Drug dosing and the patient’s seizure risk profile influence seizure susceptibility.25 Some atypical antipsychotics have been associated with diabetes and dyslipidemia, especially clozapine and olanzapine, but the cause has not been established.26

### CLINICAL FEATURES

#### Acute Overdose

In overdose, antipsychotic medications produce signs and symptoms that are exaggerations of the clinical effects. Most patients will develop symptoms within a few hours. Central nervous system (CNS) depression is universally present, ranging from mild sedation and confusion to coma and loss of brainstem reflexes. Airway reflexes can be impaired. Respiratory depression can occur after a massive overdose with profound CNS depression. Pupils can be of any size. Mild orthostatic hypotension is a common finding from alpha-adrenergic blockade. Overdose with low-potency antipsychotics can cause an anticholinergic delirium. EPS has been reported with the traditional and atypical antipsychotics.

Atypical antipsychotic overdose is similar to that of traditional antipsychotics. Overdoses are characterized by CNS depression and tachycardia.27-34 Miosis may be present, potentially mimicking opioid toxicity.35 Extremity twitching is a common finding from alpha-adrenergic blockade. Overdose with low-potency antipsychotics can cause an anticholinergic delirium. EPS has been reported with the traditional and atypical antipsychotics. Atypical antipsychotic overdose is similar to that of traditional antipsychotics. Overdoses are characterized by CNS depression and tachycardia.27-34 Miosis may be present, potentially mimicking opioid toxicity.35 Extremity twitching is a common finding from alpha-adrenergic blockade. Overdose with low-potency antipsychotics can cause an anticholinergic delirium. EPS has been reported with the traditional and atypical antipsychotics.

#### Acute Extrapyramidal Syndromes

*Acute dystonia* manifests as involuntary motor tics or spasms that most often involve the facial, neck, back, or limb muscles.
Dystonic reactions usually develop within the first several doses of treatment or after a large increase in dosage.\textsuperscript{37} Oculo-gyractic crisis, characterized by continuous rotatory eye movements, has also been reported. \textit{Laryngeal dystonia} is a rare but \textit{lifethreatening form of dystonia that manifests as stridor, difficulty breathing, or a choking sensation.}\textsuperscript{38,39} Increased risk of death due to choking has been documented in schizophrenia patients.\textsuperscript{40}

\textit{Akathisia}, a subjective feeling of restlessness associated with objective motor restlessness, is often mistaken for worsening agitation, leading incorrectly to an increase in antipsychotic dose. Akathisia usually develops within the first few days of treatment,\textsuperscript{38} but 40% of patients given 10 mg of intravenous (IV) prochlorperazine developed akathisia within 1 hour.\textsuperscript{41}

A \textit{parkinsonian syndrome} of bradykinesia, masked facies, shuffling gait, muscular rigidity, and resting tremor frequently develops during the first weeks of therapy with low-potency and high-potency neuroleptic-antipsychotic agents. \textit{Perioral tremor (rabbit syndrome)}, in which the lip and nose move around together (like a rabbit) after prolonged use of antipsychotic medication.\textsuperscript{38,43,44}

Respiratory dyskinesia, a variant of TD, is characterized by orofacial dyskinesia, dyspnea, dysphonia, and respiratory alkalosis. This chronic disorder often goes undiagnosed and can cause repeated bouts of aspiration pneumonia.

\section*{Tardive Dyskinesia}

TD is a chronic movement disorder induced by prolonged use of antipsychotic medication. Typical signs of TD include quick, involuntary movements of the face (blinking, grimaces, tongue movements, and chewing), extremities, or trunk. Twenty percent of patients treated with long-term traditional antipsychotics are affected. The risk of development is much lower with the atypical agents. TD is difficult to treat and frequently permanent. Reducing the antipsychotic dose or changing to an atypical agent should be considered. TD improves in many patients switched to clozapine, but further clinical trials are needed to study other atypical antipsychotic agents.\textsuperscript{38,43,44}

Respiratory dyskinesia, a variant of TD, is characterized by orofacial dyskinesia, dyspnea, dysphonia, and respiratory alkalosis. This chronic disorder often goes undiagnosed and can cause repeated bouts of aspiration pneumonia.

\section*{Neuroleptic Malignant Syndrome}

NMS is a serious idiosyncratic drug reaction that typically develops during the first month of therapy but has occurred during stable drug regimens. Risk factors include rapid drug loading, high dosage, high-potency antipsychotics, parental formulations, dehydration, preceding psychomotor agitation, and previous episodes of NMS.\textsuperscript{45,46} Other medications may contribute to NMS, including lithium, which inhibits dopamine secretion, as well as withdrawal from dopaminergic agents used to treat Parkinson’s disease.\textsuperscript{11,47,48} The incidence of NMS in patients treated with antipsychotics is approximately 0.02%, which is significantly lower than previous estimates of 3%.\textsuperscript{45} The atypical antipsychotic agents, including clozapine, risperidone, olanzapine, quetiapine, and aripiprazole, have been associated with NMS.\textsuperscript{45,50}

Table 159-2 lists the diagnostic criteria for NMS. Other features of NMS may include sialorrhea, dysarthria, dysphagia, metabolic acidosis, liver function elevations, sodium imbalance, dehydration, elevations in serum catecholamines, coagulopathy, generalized slowing on the electroencephalogram (EEG), pulmonary embolism, and renal failure.\textsuperscript{46} Atypical presentations may lack full diagnostic criteria for NMS.\textsuperscript{50,52}

Most patients develop the cardinal features of altered mental status, muscle rigidity, hyperthermia, and autonomic nervous system instability over several hours to days. However, the signs of NMS may develop gradually and in any order.\textsuperscript{53} Agitation, often mistaken for worsening psychosis, may occur first. Physicians should consider discontinuing antipsychotic drugs in a patient who has developed one or more of the major manifestations of NMS. Most episodes resolve within 2 weeks after cessation of the offending medication, but some cases have lasted up to 6 months.\textsuperscript{54,55}

\section*{Cardiovascular Toxicity and Dysrhythmias}

The most common cardiac effect is sinus tachycardia with a normal QRS duration. If QRS prolongation is present, then another drug effect should be suspected. QT prolongation has been reported during therapeutic dosing of many antipsychotic agents. Therapeutic doses of thioridazine followed by ziprasidone prolonged the QT interval more than did risperidone, olanzapine, quetiapine, or haloperidol.\textsuperscript{20,21} QT prolongation associated with TDP is a well-described adverse effect of thioridazine, mesoridazine, droperidol, sertindole, and high-dose IV haloperidol.\textsuperscript{14,16,18,36-38} Among typical agents, thioridazine carries the greatest risk of cardiotoxicity.\textsuperscript{16,39} Among atypical agents used during overdose, ziprasidone carries the greatest risk of QTc prolongation.\textsuperscript{40-65} QT prolongation should be considered a “class effect” of all antipsychotic medications, but the clinical significance of QTc prolongation and the risk of TDP are not known.

Atrioventricular nodal block is a rare complication of overdose with chlorpromazine, thioridazine, and other older neuroleptics.\textsuperscript{46}

\section*{Agranulocytosis}

Clozapine produces agranulocytosis, with 75% of occurrences developing within the first 18 weeks after initiation of therapy, peaking at 3 months.\textsuperscript{22} The concomitant use of other bone marrow-suppressing agents (e.g., carbamazepine) should be
avoided. Clozapine administration must be halted if the total white blood cell count falls below 3000 cells/mL or if the absolute neutrophil count is less than 1500 cells/mL. Agranulocytosis has not been reported after an acute overdose. Olanzapine, whose chemical structure is similar to that of clozapine, has been associated with neutropenia and agranulocytosis. All patients recovered after discontinuation of olanzapine.67

Seizures

Antipsychotic medications can lower the seizure threshold and induce epileptiform EEG abnormalities in many asymptomatic patients.68 However, antipsychotic-induced seizures are rare except for clozapine, which causes a dose-related increase in risk of seizures (approximately 5% at high doses). Antipsychotics can be prescribed for patients with known seizure disorder.68-70

- **DIFFERENTIAL CONSIDERATIONS**

Differential diagnostic considerations include a broad list of agents and clinical conditions that produce altered mental status, orthostatic hypotension, anticholinergic syndrome, seizure, QT prolongation, or TDP. Although the signs of NMS are similar to those of serotonin syndrome and heatstroke, the etiologies of these conditions are quite different (Table 159-3). Malignant hyperthermia should be considered in patients receiving inhalational anesthetics or succinylcholine.

- **DIAGNOSTIC STRATEGIES**

Blood levels are neither readily available nor helpful in the management of an overdose with antipsychotic medication. As with any patient who presents with altered mental status, blood glucose and pulse oximetry readings should be obtained immediately. Other testing, such as brain computed tomography, lumbar puncture, serum acetaminophen measurement, and electrolyte measurements, may be required to screen for other causes. Olanzapine and clozapine have been associated with new-onset diabetes with ketoacidosis.3

An electrocardiogram (ECG) should be obtained in patients with significant antipsychotic overdose and in symptomatic patients taking thioridazine, mesoridazine, droperidol, or sertrindole. Patients receiving high-dose IV haloperidol or droperidol for sedation require cardiac rhythm monitoring. If QT prolongation is present, serum potassium, calcium, and magnesium levels should be measured.

Patients who develop NMS, parkinsonism with marked muscle rigidity, or prolonged seizures are at risk for rhabdomyolysis and should have serum creatine kinase (CK), renal function, and urine myoglobin measured. A chest radiograph should be obtained if pulmonary aspiration is suspected. Patients taking clozapine or olanzapine who present with infection or fever should be checked for leukopenia.

*Other clinical entities to consider in the diagnosis of these conditions include Addison’s syndrome, central nervous system infection, delirium tremens, hypocalcemia, hypoglycemia, hyponatremia, intracranial hemorrhage, lethal catatonia, poisoning (e.g., amphetamines, anticholinergics, cocaine, nicotine, salicylates, sympathomimetics, strychnine, theophylline), sedative-hypnotic drug withdrawal, sepsis, status epilepticus (including nonconvulsive status), tetanus, thalamic infarct, thyroid storm, and psychotic agitation.

MAOIs, monoamine oxidase inhibitors; SSRIs, selective serotonin reuptake inhibitors.
MANAGEMENT

Acute Overdose

Treatment is supportive; no specific antidote exists for antipsychotic medication overdose. Endotracheal intubation may be required to prevent aspiration or, less often, to support respiration. Hypotension is generally mild and responds to IV crystalloids. A vasopressor with alpha-adrenergic receptor agonism, such as norepinephrine, may be used if needed. If sedation and miosis suggest opioid intoxication, a trial of naloxone is warranted. Physostigmine and flumazenil are best avoided because of the risk of precipitating seizures. Activated charcoal has no proven benefit. Activated charcoal should not be administered to a patient with a nonprotected airway to avoid aspiration of charcoal.

Acute Extrapyramidal Syndromes

Diphenhydramine, 25 to 50 mg IV, intramuscularly, or orally, or benztropine, 1 or 2 mg intramuscularly or orally, will usually control dystonic reactions. Benzodiazepines may also be effective. Akathisia can be treated with a lipophilic beta-adrenergic blocker (e.g., propranolol), anticholinergic agents, or benzodiazepines. Patients with EPS who respond to diphenhydramine or benztropine should continue on therapy for at least 48 hours to prevent recurrence. In addition, patients should be referred to their treating physician, who may reduce the antipsychotic dose or change to an atypical agent as necessary. Benzotropine, diphenhydramine, and the older antipsychotic medications all cause anticholinergic effects, so combination therapy may worsen dry mouth, blurred vision, and urinary retention.

QT Prolongation and Torsades de Pointes

Correction of hypokalemia, hypomagnesemia, and hypocalcemia shortens the QT interval. Treatment of TDP includes IV magnesium sulfate, overdrive pacing, and possibly isoproterenol. Administration of antiarrhythmic drugs that prolong the QT interval should be avoided.

Neuroleptic Malignant Syndrome

Treatment of NMS consists of supportive care and discontinuation of the offending medication. Agitation, psychomotor hyperactivity, and muscular rigidity should be treated with liberal doses of IV benzodiazepines. Lorazepam can be administered IV 1 or 2 mg every 3 minutes until muscle rigidity improves, to a maximum dose of 10 mg. In refractory cases or cases at risk of aspiration, rapid sequence induction, endotracheal intubation, and neuromuscular blockade with a nondepolarizing agent (e.g., rocuronium and vecuronium) are required. Hyperthermia should be managed with IV fluids and active external cooling with mist and fans. If rhabdomyolysis is present, IV hydration and urinary alkalization are used to prevent renal damage.

Bromocriptine and amantadine have been suggested as treatments for NMS but do not consistently show a benefit. Bromocriptine is administered orally or via nasogastric tube, beginning with 5 mg every 8 hours and titrated to a maximum of 20 mg per dose. The dose of amantadine for NMS is 200 mg orally every 12 hours. Response to therapy requires at least 24 hours. Bromocriptine has been linked to stroke, seizure, myocardial infarction, and severe hypertension in lactating or postpartum women, but not during treatment of NMS.

Dantrolene, which inhibits the release of calcium from the sarcoplasmic reticulum, has also been suggested for NMS but has no proven benefit. Because the muscular rigidity of NMS is thought to be due to dopamine blockade in the CNS rather than a muscle abnormality, dantrolene offers no advantage over benzodiazepines and neuromuscular blockade.

DISPOSITION

All patients with NMS and overdose patients with hypotension, coma, torsades de pointes, or airway compromise should be admitted to a critical care unit. Patients with a prolonged QT interval (QTc > 460 msec) and all patients with significant ingestions of thioridazine or mesoridazine should have at least 12 hours of cardiac monitoring. Patients with less severe signs of toxicity should be observed in the emergency department for a minimum of 4 hours from the time of ingestion, with hospitalization for persistent or worsening signs and symptoms. Criteria for hospital discharge include return to normal mental status and resolution of any vital sign, metabolic, and ECG abnormalities. Psychiatric consultation may be necessary to assess the risk of suicide.
Opioid is a term that applies to all natural, synthetic, and semi-synthetic agents with morphine-like actions. It is more inclusive than the term *opiate*, which refers only to natural agents. Both terms are derived from *opium*, the Greek word for juice in reference to poppy juice. Poppy juice contains more than 20 distinct natural alkaloids with morphine-like activity. The term *narcotic* refers to any agent that induces sleep and is nonspecific. Although the term narcotic persists, primarily in legal contexts, opioid is more precise and is the correct medical term for the family of agents that act on opiate receptors in the body. Finally, the term *endorphin* applies to any of the three endogenous opioid families: enkephalins, beta-endorphins, and dynorphins.1

Pharmacologic actions of opioids involve the gastrointestinal system, genitourinary system, cardiovascular system, pulmonary system, and central nervous system (CNS) and cause characteristic clinical effects. Sedation and analgesia are the most common therapeutic goals of opioid medications, which are available alone or in combination with other agents (e.g., acetaminophen and salicylates) for these purposes. Additional therapeutic goals of opioids and combination preparations include antitussive and antidiarrheal effects.

Misuse of pharmaceutical opioid preparations and use of illicit opioids are significant problems in the United States. According to the 2006 National Survey on Drug Use and Health, 506,000 Americans age 12 years or older have used heroin, including 338,000 current heroin users.2 Injection is the most common route, followed by inhalation, smoking, and ingestion. Since the early 1990s, there has been a trend toward inhalation rather than injection. Prescription pain medications are used for nonmedical means by 5.2 million users in comparison to only 2.4 million cocaine users.2 Opioids are second to sedatives/hypnotics/antipsychotics for substances involved in reported fatal exposures.3 A multistate epidemic of nonpharmaceutical fentanyl-related overdoses resulted in more than 1000 deaths from April 2006 to March 2007.4

**Pathophysiology and Pharmacology**

**Toxicity**

Opioids include therapeutic agents and illicit substances. Toxicity occurs as a result of intentional overdose, intentional abuse, or adverse effect of therapeutic use. Although different opioids have receptor preferences in therapeutic or low doses, this specificity is lost at higher doses.

Opioids are well absorbed after gastrointestinal (oral and rectal) or parenteral administration but also through nasal, buccal, pulmonary, and transdermal routes, depending on the lipid solubility of the specific opioid.7 Heroin is usually abused through intravenous and subcutaneous routes, but it is also absorbed after nasal administration because it is lipid soluble.7 In general, opioid toxicity is less pronounced but more prolonged with oral ingestion than with parenteral administration.1 Absorption of opioids after oral administration occurs in the small intestine. With therapeutic doses, absorption is complete within 1 or 2 hours. Absorption and clinical effects of toxicity may be prolonged after overdose, however, because gastric emptying is delayed.

Most opioids have a large volume of distribution. Clinical effects depend on lipid solubility, which affects the ease with which opioids and their metabolites cross the blood-brain barrier. All opioids undergo hepatic metabolism and renal elimination, and variations in hepatic and renal function are

---

important because metabolite activity may contribute to clinical effects and toxicity.1 The half-lives of meperidine and normeperidine are prolonged with cirrhosis, and the elimination of normeperidine is decreased with renal insufficiency. These conditions increase the likelihood of normeperidine-related seizures, as do multiple or large doses.8

The pharmacokinetics of the specific agent determine the clinical course of opioid toxicity. Heroin peaks in the serum within 1 minute of intravenous injection, 3 to 5 minutes of intranasal administration, and 10 minutes of subcutaneous injection. Heroin’s lipophilic nature allows for rapid transport across the blood-brain barrier into the CNS. In the CNS and blood, heroin is rapidly hydrolyzed to 6-monoacetylmorphine and then morphine (less lipid soluble). In the liver, morphine undergoes conjugation with glucuronic acid to form more water-soluble compounds that are excreted by the kidneys.9

Withdrawal

Because the half-life of heroin is 30 minutes and the half-life of methadone is 15 to 40 hours, withdrawal symptoms occur 4 to 6 hours after discontinuation of heroin compared with 24 to 48 hours after discontinuation of methadone.6,10 Duration of symptoms is 7 to 10 days and 2 weeks, respectively. The degree of physical dependence that has developed is also important. With chronic opioid exposure, cellular adaptation results in upregulation of cyclic adenosine monophosphate (cAMP). When either the exposure is discontinued or an antagonist is administered, the result is a temporary elevation of cAMP levels and increased sympathetic activity above a normal baseline.

■ CLINICAL FEATURES

Toxicity

The toxidrome of opioid toxicity is CNS depression, respiratory depression, and miosis. Other potential findings in opioid toxicity are associated with toxicity from any opioid, but some features are unique to a specific agent or route of exposure.

Neurologic

CNS depression is a well-recognized manifestation of opioid toxicity. Hypoxia from CNS depression and respiratory depression also causes many neurologic complications. Dysphoria and acute psychosis may occur with an agonist-antagonist opioid. Excitatory effects may occur with opioid toxicity. Hypertonicity, myoclonus, and seizures have been reported with overdose of the synthetic opioids meperidine and propoxyphene. Meperidine-related seizures are probably caused by accumulation of normeperidine, especially after multiple or large doses or in patients with hepatic or renal insufficiency. Seizures may also result from hypoxia with overdose of any opioid.

Parkinsonian symptoms in intravenous drug abusers have been attributed to 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), an unintended side product produced during synthesis of a meperidine analogue in street laboratories. MPTP injection is associated with accumulation of an MPTP metabolite in CNS cell mitochondria, focal lesions in the substantia nigra, and a syndrome clinically indistinguishable from idiopathic parkinsonism. The syndrome is irreversible in some patients.11

Spongiform leukencephalopathy has been associated with inhalation of heated heroin, a practice known as “chasing the dragon.” Patients present with psychomotor retardation, dysarthria, ataxia, tremor, and other neurologic abnormalities.12 This syndrome is incompletely understood but is thought to be related to a combination of mitochondrial injury and hypoxia.13 One report also associates heroin-induced movement disturbance with basal ganglia lesions.14

Serotonin syndrome is a clinical triad of mental status changes, autonomic instability, and neuromuscular changes (see Chapter 149) and may be fatal. Most cases involve an interaction between a serotonergic agent and a second agent, usually a selective serotonin reuptake inhibitor or a monoamine oxidase inhibitor. Meperidine and dextromethorphan have serotonergic properties and have been associated with serotonin syndrome.8

Respiratory

Opioids decrease respiratory rate and tidal volume in a dose-dependent manner by suppressing the sensitivity of the medullary respiratory center to hypercapnia.1 Although it initially remains intact, the hypoxic drive is overridden in severe poisoning or when antagonistic stimuli (e.g., pain) are blocked. Overdose of an agonist-antagonist agent produces less significant respiratory depression, presumably because of mu receptor antagonism (Table 160-1). Central sleep apnea is associated with long-term opioid use and also occurs in those with acute increased opioid use from baseline. Continuous positive airway pressure is usually ineffective for treatment of sleep apnea in these patients.15

Bronchospasm is rare with heroin use in asthmatic and non-asthmatic patients and occurs mostly after inhalational exposure, but other routes are also implicated. The bronchospasm is often severe, prolonged, and refractory to beta-agonist therapy. Patients may require mechanical ventilation for several days. It is unclear whether the heroin, an adulterant, or a combination triggers the bronchospasm and whether the response is histamine mediated or the result of direct irritation.7

Acute lung injury occurs with therapeutic opioid use but is much more common after overdose.16 The capillary leak is likely from hypoxia rather than a direct drug effect.

Ophthalmologic

In more than 90% of heroin overdoses, stimulation of mu receptors in the Edinger-Westphal nuclei of the third nerve results in miosis.17 Miosis is not typically seen with meperidine, propoxyphene, or diphenoxylate-atropine (Lomotil) overdose. Toxicity from agonist-antagonists (e.g., pentazocine) or multiple agents may not produce miosis.

Otolaryngologic

Rapidly progressive sensorineural hearing loss has been reported with the use of hydrocodone. Genetic polymorphism producing altered metabolism and/or comorbidities have been suggested as causative factors.18

Cardiovascular

Opioids cause mild hypotension and relative bradycardia. Hypotension seems to be from histamine release and can be blocked by antihistamines (H1 antagonists).19 The hypotension is typically orthostatic and resolves with supine positioning. Propoxyphene and its metabolite, norpropoxyphene, may cause sodium channel blockade similar to that of type IA antidysrhythmic agents to produce widening of the QRS complex.20

*Equivalent to 10 mg of intramuscular morphine.
†Varies with the drug and route of administration. In addition, the effects of a dose in any particular patient depend on multiple factors, including age, weight, and comorbid conditions. After intramuscular administration, very fast means 5 to 30 minutes, fast means 15 to 60 minutes, and slow means 1 to 4 hours. After oral administration, these time definitions are approximately doubled.

**Gastrointestinal**

Nausea and vomiting are common with therapeutic opioid use and also with overdose. Mechanisms include opioid-induced delayed gastric emptying, direct stimulation of the chemoreceptor trigger zone, and vestibular stimulation. Antihistamines and dopamine antagonists (e.g., chlorpromazine) may be effective in treatment.

Decreased gastrointestinal motility is a common finding with therapeutic use and overdose of opioids. Severe cases may develop ileus. Increased biliary tract pressures and choledochoduodenal sphincter spasm occur with therapeutic dosing of many opioids, including morphine, meperidine, and codeine. Spasm is not always reproducible within the same patient but seems related more to individual susceptibility than to a specific agent. Presenting clinical symptoms mimic biliary colic and may respond to naloxone or glucagon.

**Genitourinary**

Opioids can cause urinary retention from urethral sphincter spasm and decreased detrusor tone. Alpha-adrenergic antagonists may reverse this effect. Glomerulosclerosis and renal amyloidosis are seen in end-stage “heroin nephropathy” of chronic opioid addicts.

**Dermatologic**

Pruritus, flushing, and urticaria occur after administration of certain opioids that release histamine (e.g., morphine) and do not represent a true allergy. Pruritus and erythema are often localized to the area of injection (e.g., along the vein through which the morphine was administered). Symptoms typically are controlled easily with antihistamines. Although all opioids have the potential to stimulate mast cell degranulation and histamine release, some (e.g., fentanyl) release only clinically negligible amounts of histamine and thus have good hemodynamic stability profiles.

**Metabolic**

Hypoglycemia occurs after opioid overdose, but the mechanism is unclear. Co-ingestants, especially ethanol, may contribute to this finding. Hypothermia has been reported, but the mechanism is unclear. Hyperthermia should prompt a search for infectious complications, particularly in intravenous drug users, and for co-ingestants (e.g., cocaine) or adulterants (e.g., tripelemamine and scopolamine). “Cotton fever” is reported in intravenous drug users who strain suspended drug through cotton balls or cigarette filters to remove particulates. Filters are boiled to extract residual drug when supply is low. Cotton is a known pyrogen and can cause a benign fever in patients who subsequently “shoot the cottons” or inject the extracted residue from the filters.

**Withdrawal**

Opioid withdrawal occurs in tolerant individuals when opioid use is discontinued or an antagonist is administered. Increased sympathetic discharge and adrenergic hyperactivity are responsible for the clinical symptoms and signs. In contrast to the typical toxidrome of opioid toxicity (CNS and respiratory depression and miosis), withdrawal is associated with CNS excitation, tachypnea, and mydriasis. Pulse and blood pressure are also increased. Although these can be uncomfortable, they are typically not life-threatening.

Neurologic manifestations are prominent in opioid withdrawal. Restlessness, agitation, and anxiety are virtually universal, and seizures may rarely occur. Cognition and mental status are unaffected. Dysphoria and drug craving may be severe and prolonged.

Nausea, vomiting, diarrhea, and abdominal cramps are common in withdrawal. They can be significant and lead to dehydration and electrolyte abnormalities. Other symptoms may also include diffuse myalgias and insomnia with piloerection, yawning, lacrimation, rhinorrhea, and diaphoresis.
The diagnosis of opioid intoxication is usually based on history and physical examination. Diagnostic studies rarely assist in the evaluation of patients suspected of opioid overdose. Other than hypoglycemia, specific laboratory abnormalities are not seen. When the patient has hypoxemia and pulmonary rales, a chest radiograph should be obtained to evaluate for acute lung injury. In the appropriate circumstances, an abdominal radiograph may identify packets of opioids or other illicit substances in a body packer. A case of QRS widening is thought to be associated with propanolol overdose but has not been validated. If cardiac monitoring shows a prolonged QRS, a 12-lead electrocardiogram is advisable. With ingestion of an unknown opioid preparation, acetaminophen and salicylate levels should be checked because many prescription opioids are available in combination products. Likewise, many illicit opioid users are exposed to additional drugs and contaminants.

Although opiates are detected on most qualitative urine toxicology screens, these are rarely helpful in acute situations. On some assays, several synthetic opioids are also detected because they cross-react or because they are metabolized to opiates, which are then excreted. Other agents, such as fentanyl and its derivatives, are missed on urine screens. Poppy seed ingestion can lead to a positive opiate screen for morphine and codeine; however, detection of 6-monoacetylmorphine, a specific metabolite of heroin, can confirm heroin use. As with opioid toxicity, no diagnostic test exists for opioid withdrawal.

Differential Considerations

The diagnosis of opioid intoxication is usually obvious, based on history and physical examination, although patients with other intoxications or nontoxicologic conditions may have a similar physical examination. Other drugs that should be considered are clonidine (or a related drug), tramadol, valproic acid, γ-hydroxybutyrate, and sedative-hypnotic agents. The differential diagnosis encompasses all causes of depressed mental status, but the coexistence of miosis and respiratory depression greatly narrows the possibilities.

Opioid withdrawal is usually a straightforward diagnosis, and the patient often reveals it as the chief complaint. Simultaneous intoxication with, or withdrawal from, other classes of agents, especially CNS depressants and stimulants, may be seen.

Management

Attention to the airway, oxygenation, and ventilation is of vital importance in patients with opioid toxicity. If reversal is not achieved with antidote therapy, appropriate interventions include airway protection and ventilatory support. Patients with acute lung injury may require oxygen and positive-pressure modalities, such as bilevel positive airway pressure, continuous positive airway pressure, or mechanical ventilation with positive end-expiratory pressure. Circulatory support usually does not require more than a crystalloid infusion. Most opioids have a large volume of distribution and cannot be cleared by dialysis. There are no clinically effective techniques for enhanced elimination of opioids.

Gastrointestinal Decontamination

Gastrointestinal decontamination is often unnecessary because the antidote can reverse the effects. Whole-bowel irrigation can hasten passage of drug packets from body packers or patients with ingestions involving opioid combination products or multidrug ingestions. A single early dose of activated charcoal (1 g/kg in children and 50–100 g in adults) may be beneficial in some patients because gastrointestinal motility may be reduced.

Antidote

Naloxone, a pure opioid antagonist, is the antidote most frequently used to reverse opioid toxicity. Naloxone has a rapid onset of action. For reversal of systemic opioid toxicity it is ineffective after oral administration secondary to the first-pass effect, but intravenous, subcutaneous, intramuscular, inhalational, and endotracheal routes can be used. Naloxone competitively binds opioid receptors and can reverse all the receptor-mediated actions of opioids. Naloxone is indicated for patients with opioid intoxication who have significant CNS or respiratory depression. The initial intravenous dose is 0.4 to 2 mg for adults and children, but 10 mg may be required to obtain a clinical response for synthetic opioids.

Naloxone can precipitate acute withdrawal in chronic opioid users. In this population, the dose should be started at 0.2 mg and slowly titrated. The duration of action of naloxone is 1 or 2 hours. Consequently, either repeat doses or a continuous infusion of two thirds of the effective initial dose per hour may be required.

Naloxone has an excellent safety profile. Acute lung injury, hypertension, and dysrhythmia have been associated with use of naloxone after general anesthesia and in patients with underlying cardiac or pulmonary disease. Whether naloxone is the cause of these complications is unproven. Idiosyncratic reactions and sympathetic discharge with precipitation of acute withdrawal have been proposed as explanations. The risk may be greater in those with ongoing hyperventilation prior to naloxone administration. Complete clinical recovery in response to naloxone is strongly suggestive of opioid overdose. Other intoxications, including valproic acid, clonidine, tramadol, captopril, and ethanol intoxication, may improve to lesser degrees with naloxone. Naloxone has been given to patients who have ingested these agents because of a presentation similar to opioid intoxication or suspicion of a mixed exposure that included opioids. The mechanism of these responses to naloxone is not established. Some of these drugs may have activity at opioid receptors.

Nalmefene, another opioid antagonist, has a long half-life (8–11 hours) and duration of clinical effect. Intravenous nalmefene has a rapid onset of action in reversing opioid-induced CNS and respiratory depression. Alternate administration routes are oral, subcutaneous, and intramuscular. The initial intravenous dose is 0.5 to 1.5 mg (pediatric dose not established). Higher doses have been used but are associated with increased risk of adverse effects. When a clinical response has been achieved with nalmefene, repeat doses or continuous infusions are generally not required; however, the duration of withdrawal symptoms may be longer with nalmefene. Naloxone remains the preferred antidote in patients at risk for withdrawal or other adverse effects and in patients with anticipated short duration of opioid toxicity. Seizures associated with opioid toxicity resolve with correction of hypoxia or administration of benzodiazepines.

Withdrawal

Opioid withdrawal is not life-threatening, but the potentially serious manifestations mandate attention to supportive and symptomatic care. When withdrawal is produced by adminis-
 Withdrawal

Patients with opioid withdrawal may be managed as outpatients. Clonidine may alleviate some of the symptoms of withdrawal but has a high incidence of postural hypotension. Patients with refractory complications (e.g., vomiting, dehydration, and electrolyte abnormalities) and patients with an uncertain diagnosis may require hospitalization. Some patients may need to be detoxified before entering chemical treatment programs. Substance abuse counseling and establishment of outpatient program referral should be completed before discharge.

KEY CONCEPTS

- Diagnosis of opioid intoxication is based on history, physical examination, and response to naloxone.
- The opioid toxidrome includes three prominent findings—CNS depression, respiratory depression, and miosis—but these may not be present in every patient.
- Early administration of reversal agents and airway management and attention to oxygenation and ventilation are crucial to management of patients with opioid toxicity.
- The duration of action of many opioids, especially after overdose, is significantly longer than that of naloxone. Patients responsive to naloxone should be observed for recurrence of opioid toxicity after the effect of naloxone has resolved.
- Opioid withdrawal syndrome does not include altered cognition. Patients with known or suspected opioid withdrawal who also have altered cognition should be evaluated for another etiology of the altered cognition.

**PERSPECTIVE**

**Pesticides**

Pesticides, a generic term used to refer to all pest-killing agents, include numerous chemicals intended for use as insecticides, herbicides, rodenticides, fungicides, and fumigants. Many of these chemicals are general protoplasmic poisons affecting a wide range of organisms, including humans. Although space does not allow a comprehensive discussion of each individual chemical that may produce human toxicity, numerous chemical classes are commonly used as pesticides. These classes have associated characteristic clinical pictures that are important to recognize because patients with acute (and occasionally chronic) exposures to these agents come to the emergency department. In addition, other pesticides with particularly unique mechanisms of toxic effects are described.

**ORGANOPHOSPHATE AND CARBAMATE INSECTICIDES**

The organophosphate insecticide triethyl pyrophosphate was first synthesized in 1859 but was not used to replace nicotine as a pesticide until World War II. After World War II, these compounds were used as chemical warfare agents, as organophosphorus and carbamate insecticides, and as medicinal agents. After the negative publicity associated with the organochlorine dichlorodiphenyltrichloroethane (DDT), organophosphorus insecticides soon became some of the most common pesticides for home and industrial use. Since the late 1990s, with the increased awareness of terrorism, nerve agents have gained prominence as weapons of mass destruction.1

**Principles of Disease**

Organophosphorus insecticides are highly lipid soluble and are readily absorbed via dermal, gastrointestinal (GI), and respiratory routes.2 This lipid solubility results in the storage of organophosphorus compounds in body fat, making toxic systemic levels possible from gradual or rapid accumulation from repeated low-level exposures. The parent compound and its metabolites are acetylcholinesterase inhibitors, and many parent organophosphorus compounds are less potent than their metabolites (e.g., parathion to paraoxon), which may result in delayed onset of clinical toxicity.

Organophosphorus pesticides work by persistently inhibiting the enzyme acetylcholinesterase, the enzymatic deactivator of the ubiquitous neurotransmitter acetylcholine. Because of the global penetration of organophosphorus compounds, inhibition occurs at tissue sites (true acetylcholinesterase and represented by erythrocyte or red blood cell [RBC] cholinesterase) and in plasma (circulating pseudocholinesterase).3,4 Inhibition of cholinesterase results in the accumulation and subsequent prolonged effect of acetylcholine at a variety of neurotransmitter receptors, including the sympathetic and parasympathetic ganglionic nicotinic sites, postganglionic cholinergic sympathetic and parasympathetic muscarinic sites, skeletal muscle nicotinic sites, and central nervous system sites (Fig. 161-1).5

**Clinical Features**

**Signs and Symptoms**

The accumulation of acetylcholine results in a classic cholinergic syndrome, manifested by hyperactivity of cholinergic responses at the receptor sites indicated previously. The clinical syndrome of muscarinic acetylcholinesterase inhibition is commonly called the SLUDGE syndrome (Table 161-1). This syndrome represents postganglionic acetylcholine-induced hollow end-organ general hypersecretion,2 resulting in clinical findings that include miosis pupils, lacrimation, rhinorrhea, sialorrhea, bronchorrhea, vomiting, diarrhea, and urinary incontinence. Bradycardia is a classic sign of the cholinergic syndrome, but the increased release of norepinephrine from postganglionic sympathetic neurons precipitated by excess cholinergic activity at sympathetic ganglia may result in normal or even tachycardic heart rates (nicotinic effect). Sympathetic hyperactivity can cause diffuse diaphoresis, although this response is mediated by cholinergic receptors at preganglionic (nicotinic) and postganglionic (muscarinic) sites. The most lethal components of acetylcholinesterase inhibition occur in the brain and neuromuscular junction. A combination of sympathetic stimulation, involvement of the N-methyl-D-aspartate receptor, and enhanced acetylcholine concentrations can lead to seizures.5 At the neuromuscular junction, excess acetylcholine causes hyperstimulation of the muscles with secondary paralysis. Because the diaphragm is affected, cholinesterase poisoning leads to respiratory arrest.6

Although the usual clinical picture of acute organophosphorus poisoning is impressive, toxicity from gradual, cumulative exposure may be much more subtle. These patients commonly exhibit vague confusion or other central nervous system complaints; mild visual disturbances; or chronic abdominal cramping, nausea, and diarrhea.7
Acetylcholinesterase inhibitors produce direct toxic effects on the central nervous system leading to neurologic signs of confusion, combativeness, seizures, and coma. Status epilepticus may occur in severely poisoned patients. Structural central nervous system damage may occur if seizures are not terminated rapidly.9

A unique effect of organophosphorus insecticides results from “aging,” the irreversible conformational change that occurs when the organophosphorus agent is bound to the cholinesterase enzyme for a prolonged time. On average, for commercial organophosphorus agents some aging will occur by 48 hours, but aging may take longer. Once the enzyme has aged, an oxime antidote cannot regenerate the cholinesterase.

**Diagnostic Strategies**

Any patient with a full-blown cholinergic syndrome should be treated empirically without waiting for laboratory confirmation of decreased cholinesterase activity. Known or suspected exposure to cholinesterase inhibitors should be confirmed by ordering plasma and erythrocyte (RBC) cholinesterase levels. In acute exposures, the plasma cholinesterase levels decrease first, followed by decreases in RBC cholinesterase levels. The RBC cholinesterase level is more indicative of what is occurring at the nerve terminal.7 Patients with chronic exposures may show only reduced RBC cholinesterase activity, with a normal plasma cholinesterase level. The true reflection of depressed cholinesterase activity is found in the RBC activity, and even a mild acute exposure may result in severe clinical poisoning. RBC cholinesterase levels recover at a rate of 1% per day in untreated patients and take approximately 6 to 12 weeks to normalize, whereas plasma cholinesterase levels may recover in 4 to 6 weeks. Other studies should focus on the evaluation of pulmonary, cardiovascular, and renal function and fluid and electrolyte balance. Patients presenting with no acidosis, or only a metabolic acidosis on the arterial blood gas, have lower mortality than those presenting with a respiratory or mixed acidosis.10

**Differential Diagnosis**

Few toxins or other clinical conditions produce the same symptoms as acetylcholinesterase inhibitors. A species of mushroom, *Amanita muscaria*, historically has been mentioned in the differential diagnosis, but it actually contains alkaloids that usually produce an anticholinergic (antimuscarinic) syndrome. A variety of conditions that induce excessive vagal responses (e.g., inferior wall myocardial infarction) may also produce some signs suggesting acetylcholinesterase inhibition, but other symptoms should make the primary cause apparent.

**Management**

Treatment is directed toward four goals: (1) decontamination, (2) supportive care, (3) reversal of acetylcholine excess at muscarinic sites, and (4) reversal of toxin binding at active sites on the cholinesterase molecule. Decontamination should start in the out-of-hospital phase of care to prevent greater absorption and subsequent toxicity and to protect care providers. Decontamination is particularly important in cases of dermal poisoning; removal and destruction of clothing and thorough flushing of exposed skin may limit absorption and subsequent toxicity. Alternatively, dermal decontamination can be done with dry agents, such as military resins, flour, sand, or bentonite. Caregivers are at risk for contamination from splashes or handling of contaminated clothing. Treating personnel may be rotated

**Complications**

Seizures and pulmonary hypersecretion, or bronchorrhea and bronchoconstriction, are prominent mechanisms of early morbidity and mortality in cases of poisoning from acetylcholinesterase inhibitors. Bronchorrhea is often incorrectly called noncardiogenic pulmonary edema because the origin of the excessive pulmonary fluids is from airway secretions and not transudation of fluid across the alveolar-capillary membrane. The obstruction of upper and lower airways, the potential intrusion of these bronchial secretions into alveolar sacs, and bronchoconstriction produce hypoxia, which is the primary concern in the initial stages of poisoning.5

Nicotinic hyperstimulation of skeletal muscle determines the ultimate morbidity and mortality of acetylcholinesterase inhibitors. Signs of skeletal muscle hyperactivity include involuntary twitches, fasciculations, and hyperactive reflexes. Muscle hyperactivity eventually gives way to muscle fatigue and paralysis, including the respiratory musculature and particularly the diaphragm.6,9 Respiratory insufficiency may be delayed and result in death if not anticipated and corrected by mechanical or pharmacologic means.
to limit their exposure to the organophosphates. Caregivers should use universal precautions, including eye shields, protective clothing, and nitrile or butyl rubber gloves. In the case of ingestion, GI decontamination procedures are of questionable benefit because of the rapid absorption of these compounds. Profuse vomiting and diarrhea are seen early in ingestion and may limit or negate any beneficial effect of additional GI decontamination. Equipment, but not tissues, may be washed with a 5% hypochlorite solution to inactivate the cholinesterase inhibitor.

Because death is from airway and respiratory failure, supportive care should be directed primarily toward airway management, including suctioning of secretions and vomitus, oxygenation, and, when necessary, ventilatory support. Succinylcholine can be used for intubation but may have an extremely prolonged duration. It is preferable to use a competitive neuromuscular blocking agent, such as rocuronium, for rapid sequence intubation in these patients, but increased dosing may be necessary. Although some authors have advocated the use of beta-blockers to control tachycardia, this may increase cardiovascular instability and worsen bronchospasm. Most cardiovascular complications that occur in this setting rarely require specific therapy.

The definitive treatment of acetylcholinesterase inhibition starts with atropine. A competitive inhibitor of acetylcholine at muscarinic receptor sites, atropine reverses the clinical effects of cholinergic excess at parasympathetic end organs and sweat glands. Large doses of atropine may be required. Data suggest that the more rapid the atropinization, the faster control is obtained. Suggested dosing is 1 or 2 mg of atropine (0.02–0.05 mg/kg) intravenously, with doubling of each subsequent dose every 5 minutes until there is control of mucous membrane hypersecretion and the airway clears. If intravenous access is not immediately available, atropine may be administered intramuscularly. Patients may require 200 to 500 mg of atropine intravenously during the first hour, followed by prolonged continuous infusions of 5 to 100 mg/hr to maintain adequate secretion control. Tachycardia and mydriasis may occur at these doses, but they are not indications to stop atropine administration. The endpoint of atropinization is drying of respiratory secretions, easing of respiration, and a mean arterial pressure greater than 60 mm Hg. Animal evidence suggests that early rapid atropinization may limit seizure propagation and, in conjunction with diazepam, prevent status epilepticus. Atropine is not active at nicotinic sites and does not reverse the skeletal muscle effects (e.g., muscle fatigue and respiratory failure). Other anticholinergic medications such as diphenhydramine or ophthalmic agents may have benefit if atropine is scarce or unavailable; however, optimal intravenous dosing is not known.

The second part of acetylcholinesterase inhibition treatment is the use of an oxime, such as pralidoxime (2-PAM, Protopam) or obidoxime (Toxigonin), to regenerate the organophosphate-acetylcholinesterase complex and restore cholinesterase activity at muscarinic and nicotinic sites. There are various dosing regimens; the most common dose of pralidoxime is 1 or 2 g intravenously (pediatric dose, 25–50 mg/kg); additional doses may be given based on clinical response and serial cholinesterase levels. The medication may be given in a bolus of 1 or 2 g intravenously over 30 to 60 minutes every 4 to 8 hours or 500 mg/hr (pediatric dose, 10–25 mg/kg/hr). The World Health Organization recommends an initial dose of 30 mg/kg followed by 8 mg/kg/hr continued for at least 24 hours or, if an infusion cannot be used, 30 mg/kg every 4 hours. The infusion may be continued for several days with no adverse effects attributable to the pralidoxime; however, rapid administration can lead to hypertension, vomiting, and a transient reversible neuromuscular blockade. The ideal dose of pralidoxime should be determined by monitoring the clinical condition of the patient and serial cholinesterase levels; the patient may require higher doses of oxime than recommended here. The World Health Organization recommended infusion dose of obidoxime is 4 mg/kg followed by 0.5 mg/kg/hr; alternatively, intermittent intravenous doses of 4 mg/kg, then 2 mg/kg, every 4 hours are given. Pralidoxime and obidoxime can be administered by intramuscular injection. Indications for oxime therapy include respiratory depression/apnea, fasciculations, seizures, arhythmias, cardiovascular instability, and use of large amounts of atropine. Oxime therapy can be used whenever the patient requires more than a limited amount of atropine (2–4 mg) to completely reverse the signs and symptoms of intoxication or in any patient who requires repeated doses of atropine. Oxime therapy and atropine are synergistic.

In the past, pralidoxime was only used within the first 24 hours because of aging of the organophosphate-acetylcholinesterase complex, but not all organophosphates behave in a similar manner. Dimethyl and diethyl phosphoryl insecticides react differently at variable rates with acetylcholinesterase and oxime therapy. Many organophosphates are highly lipid soluble and slowly leach out of fat stores for up to 6 weeks, resulting in newly formed complexes with excellent reversal of the cholinesterase inhibition by pralidoxime clinically and by measurements of cholinesterase activity. Pralidoxime can also combine with unbound organophosphates and prevent their subsequent binding to nerve terminals. Even with optimal treatment, seriously intoxicated patients may require long-term supportive care, including ventilator support.

In conjunction with atropine and oxime pralidoxime, patients with agitation, seizures, and coma should be treated with adequate doses of a benzodiazepine after the airway has been secured. Although diazepam is most studied, any parenteral benzodiazepine may be used. The military has classically used diazepam autoinjectors for intramuscular use, but midazolam is the best intramuscular agent, with lorazepam as an alternate.

Sarin, soman, tabun, and VX are nerve agents that might be used in a terrorist attack. These agents have important differences from the common household or commercial organophosphorous insecticides. These agents tend to age very quickly, with tabun (GA) aging in 14 hours, sarin (GB) in 5 hours, soman (GD) in 5 or 6 minutes, and VX in 48 hours. Due to this rapid aging, reversal of nerve agent poisoning is very time sensitive. VX is an oily but highly toxic agent with low volatility. It does not readily vaporize, and because it has a low risk of inhalation, exposure is predominately transcutaneous. The other agents can be mostly dispersed into the air by explosion or vaporization, resulting in inhalation exposure. These agents do not require the extremely large doses of atropine but do require pralidoxime. See Chapter 194 for further information on treatment.

New therapies for treatment of organophosphorus poisoning, including the use of N-acetylcysteine and exogenous acetylcholinesterase, show promise in research studies. When added to anticholinergics, NMDA receptor antagonists may decrease organophosphorus compound–induced seizures.

Disposition
Because of the prolonged effects of acetylcholinesterase inhibition, most patients with significant exposures require hospital admission. Occasionally, a person with chronic exposure, depressed cholinesterase levels, and mild visual or GI symptoms may be followed on an outpatient basis; however, some
patients, particularly those exposed to fenithion, initially present with signs and symptoms of mild exposure and progress to severe, life-threatening toxicity over time.\textsuperscript{32} If plasma cholinesterase levels are available, they may be useful for treatment and disposition decisions. Asymptomatic or minimally symptomatic patients with normal or minimally depressed levels may be discharged after 4 to 6 hours with close outpatient follow-up to ensure that progressive toxicity does not occur. Patients with severely depressed levels (usually associated with significant symptoms) require admission and close monitoring, usually in a high-intensity care unit. Patients may develop rebound toxicity several days after apparently satisfactory response to initial treatment. Rebound toxicity may occur for many reasons, including persistent release of organophosphates from lipid stores.

A secondary syndrome, the intermediate syndrome (IMS), occurs 24 to 96 hours after exposure and consists of proximal muscular weakness specifically of the respiratory muscles. It is believed to be an abnormality at the neuromuscular junction. Patients with IMS present with respiratory failure several days after the acute cholinergic symptoms have resolved and may require several weeks of ventilatory support. It is theorized that this may occur as a result of inadequate initial oxime treatment or premature discontinuation of oxime therapy.\textsuperscript{6,33} Oximes may be beneficial for IMS; however, this is controversial.\textsuperscript{34} Finally, organophosphorus-delayed neuropathy has been reported as a different entity and affects an axonal enzyme, neurotoxic esterase, and leads to a peripheral sensorimotor syndrome and a history of exposure of organophosphorus or carbamate insecticides.

\section*{CARBAMATE INSECTICIDES}

Carbamate insecticides are another class of acetylcholinesterase inhibitors and are differentiated from the organophosphorus compounds by their relatively short duration of toxic effects. Carbamates inhibit acetylcholinesterase for minutes to 48 hours, and the carbamate-cholinesterase binding is reversible.\textsuperscript{2} Although the clinical picture of acute carbamate poisoning may be identical to that of organophosphate poisoning, the toxic effects are limited in duration and patients may require only decontamination, supportive care, and treatment with adequate doses of atropine. Although the duration is limited in scope, patients may become just as sick and require assisted ventilation and seizure therapy. The use of pralidoxime is controversial in carbamate poisoning; an animal study suggests that pralidoxime administration may produce greater toxicity in cases of carbaryl (Sevin) poisoning, although the author has used pralidoxime in carbaryl-poisoned humans without adverse events.\textsuperscript{35} Nevertheless, if doubt exists as to whether a severe poisoning is due to a carbamate or organophosphate, pralidoxime should be administered. It is the author’s practice to use oximes when patients present with a cholinergic toxidrome and a history of exposure of organophosphorus or carbamate insecticides.

\section*{CHLORINATED HYDROCARBON INSECTICIDES}

DDT, the prototype of chlorinated hydrocarbon insecticides (sometimes referred to as organochlorine insecticides), was first used extensively during World War II for the successful control of typhus and malaria and was used widely in the United States as a general insecticide after the war. Because of the effectiveness of DDT, many other chlorinated hydrocarbon insecticides were developed. These insecticides were used extensively in agricultural, commercial, and residential pest control. However, although these insecticides were very effective, their widespread use, long half-life, and persistence had negative ecologic repercussions. Many of these insecticides have been targeted as persistent organic pollutants by international agencies, leading to their restricted use.\textsuperscript{36}

Although chlorinated hydrocarbon insecticides are no longer used in the United States for agricultural use, \(\gamma\)-hexachlorocyclohexene, better known as lindane (Kwell), is still used as a topical medicinal agent for the treatment of head lice and scabies. As a result, lindane is probably the most common cause of toxicity from an organochlorine compound in the United States. Given its toxicity, lindane is no longer a first-line agent for the treatment of scabies.\textsuperscript{37} In 2001, California issued a ban on the use and sale of lindane, and other states are considering a ban on lindane.\textsuperscript{36}

\section*{Principles of Disease}

Chlorinated hydrocarbon pesticides are highly lipid soluble. They are readily absorbed through dermal, respiratory, and GI routes.\textsuperscript{38} Dermal and GI exposures account for most clinical poisonings, including inappropriate external use of lindane or other compounds and the occasional accidental oral administration of lindane. Because they are so lipid soluble, these compounds are stored in fatty tissues, and repeated small exposures result in accumulation and eventual clinical toxicity.\textsuperscript{39}

Chlorinated hydrocarbon insecticides primarily affect axonal membranes, resulting in neuronal irritability and excitation. Toxicity occurs in central and peripheral neurons.\textsuperscript{40} Some of the organochlorines can inhibit the chloride channel of \(\gamma\)-aminobutyric acid (GABA) receptors, leading to decreased inhibition of the central nervous system.\textsuperscript{31} Chlorinated hydrocarbons induce hepatic microsomal enzymes and produce hepatic tumors in some animals. This potential carcinogenicity is the basis for current human health concerns, but it is only theoretical. Chlorinated hydrocarbon insecticides, including chlorinated hydrocarbon solvents, may sensititize the myocardium to circulating catecholamines and increase susceptibility to ventricular dysrhythmias, such as tachycardia and fibrillation.\textsuperscript{40}

\section*{Clinical Features}

\subsection*{Signs and Symptoms}

The primary clinical picture of acute or cumulative toxicity from chlorinated hydrocarbon pesticides is related to their neurotoxicity. Premonitory peripheral signs and symptoms, such as tremor or paresthesias, may be absent, and the first sign of toxicity may be the acute onset of seizure activity.\textsuperscript{42} Additional signs include confusion, combative ness, and muscle twitching. Untreated, continued muscle activity can lead to hyperthermia, metabolic acidosis, and rhabdomyolysis with secondary acute tubular necrosis.\textsuperscript{43} Because many of these agents are halogenated, ventricular dysrhythmias may occur from catecholamine sensitization and direct myocardial toxic effects. Immediate hepatotoxicity is unlikely without secondary hyperthermia or other metabolic complications.\textsuperscript{40,41} Long-term exposure may result in neuropsychiatric symptoms.\textsuperscript{45} Diagnosis may be difficult in chlorinated hydrocarbon pesticide exposure because the patient may be unable to provide a history. Nonhospital personnel are often in the best position to obtain information concerning pesticide availability and use and the situation surrounding the exposure. Another clue is the solvent odor and oily feel of the hydrocarbon solvent containing the highly lipid-soluble chlorinated hydrocarbon pesticides.
Diagnostic Strategies

Diagnosis must be confirmed by history or by investigation at the site of the exposure to establish the offending agent with certainty. No specific tests are readily available to confirm the diagnosis of chlorinated hydrocarbon pesticide poisoning. Some reference laboratories can measure fat and plasma levels, but results are difficult to interpret and seldom available during the acute phase of toxicity. Ancillary laboratory and other studies should be based on the clinical condition, complications, and consideration of alternative diagnoses on an individual basis.

Differential Considerations

The differential diagnosis includes virtually every condition that produces seizures. The specific diagnosis depends on obtaining the history of significant acute or chronic chlorinated hydrocarbon pesticide exposure.

Management and Disposition

Skin decontamination with soap and water may reduce toxicity in acute dermal exposure. High lipid solubility results in rapid absorption, and delayed GI decontamination is not of benefit. Elimination of some chlorinated hydrocarbon insecticides can be increased, and repeat doses of cholestyramine (4 g orally every 8 hours) given during a mass exposure of chlordecone (a chlorinated hydrocarbon insecticide) enhanced the fecal elimination of this compound.

The primary therapeutic objective is seizure control, which is best accomplished with short-acting benzodiazepines or barbiturates. Recurrent seizures or status epilepticus may require high-dose barbiturates and paralyzing agents (e.g., pancuronium or vecuronium) to prevent secondary morbidity from continuous motor activity in prolonged seizures. The seizure activity is usually self-limiting, lasting only 1 or 2 days even in severe cases.

Continuous cardiac monitoring during the acute phase is indicated because of the potential for myocardial sensitization. Ventricular dysrhythmias are most likely to occur during seizure activity because of the high circulating catecholamine levels and other metabolic abnormalities present during seizures. Dysrhythmias should be treated with beta-adrenergic antagonists, such as propranolol, metoprolol, or esmolol, to reduce the effect of catecholamines on the myocardium.

Additional treatment should focus on the complications of prolonged seizure activity, such as rapid external cooling measures for hyperthermia. Metabolic acidosis is almost always transient and resolves spontaneously without treatment. Rhabdomyolysis and myoglobinuria should be anticipated. Other complications of seizures should be treated as indicated. Because of their high lipid solubility, chlorinated hydrocarbon pesticides are distributed largely in tissues and are not amenable to hemoperfusion, dialysis, or other attempts to enhance elimination.

Patients who have acute or cumulative chlorinated hydrocarbon pesticide toxicity require hospitalization until their seizures are controlled, complications have resolved, and they have returned to their neurologic baselines; this usually occurs within 1 or 2 days. Severe complications, such as renal failure from rhabdomyolysis, may prolong the clinical course.

SUBSTITUTED PHENOLS

The substituted phenols include dinitrophenol (DNP), pentachlorophenol, and dinitroresol. These compounds have been used since the 1930s as insecticides, termicides, herbicides, and wood preservatives. They are currently used in agricultural, commercial, and residential applications, including over-the-counter preparations for home gardeners. Substituted phenols such as DNP are abused as weight-reduction agents and occasionally are used in illegitimate weight-reduction operations.

Principles of Disease

Substituted phenols are readily absorbed through the skin and GI tract, and aerosols may be absorbed through the respiratory tract. There is some potential for cumulative toxicity with repeated exposures, but much less so than with the organophosphorus and chlorinated hydrocarbon pesticides previously discussed.

Substituted phenols produce their toxicity by uncoupling cellular oxidative phosphorylation; this leads to inefficient production of high-energy phosphate substrates and increased cellular use of oxygen, glucose, and water, with subsequent excessive heat production. These compounds are commonly used during the summer when the external heat predisposes users to increased toxicity. In addition, nitro-substituted phenols may produce methemoglobinemia.

Clinical Features

Patients with substituted phenol toxicity present hypermetabolic and hyperthermic, tachycardic, tachypneic, and profusely diaphoretic. They may also have a relative hypovolemia from excessive insensible fluid losses through sweating and metabolic consumption. Loss of energy production in the brain results in neurologic changes ranging from confusion to seizures and coma. Renal and hepatic injury, and rhabdomyolysis with myoglobinuria, is common. Because phenols are generally corrosive, patients with dermal exposures often have irritation or chemical burn, and some substituted phenols, such as dinitrophenol, produce a characteristic yellow staining of the skin or mucous membranes at the site of absorption. This same staining can be found throughout the internal organs at autopsy.

Cataracts are a complication of long-term exposure. This condition was common in patients who used substituted phenols as part of a weight-reduction regimen and was partially responsible for the banning of this substance. The cataracts regress spontaneously after exposure is discontinued.

Diagnostic Strategies

Laboratory evaluation of patients with substituted phenol toxicity is aimed at identifying deficiency of aerobic metabolic substrates, including oxygen, glucose, and water. A complete blood count may reveal hemoconcentration and a nonspecific leukocytosis. Electrolyte abnormalities depend on the duration and severity of symptoms, environmental factors, and complications or underlying disease states. Arterial blood gas measurements show varying degrees of acidosis, depending on the extent of anaerobic metabolic activity due to oxidative phosphorylation uncoupling and associated tissue hypoperfusion from dehydration. Serum enzyme determinations document the extent of hepatic, renal, and skeletal muscle injury. The presence of phenolic compounds in the urine of a patient with this clinical picture strongly suggests substituted phenol pesticides as the causative agent.
Differential Considerations

Acute toxicity from substituted phenol poisoning is difficult to distinguish from typical environmental heat-related emergencies or toxicity from sympathomimetics or salicylates. Continued evidence of hypermetabolic activity and metabolic acidosis after routine cooling measures, rehydration, and other supportive care should lead to a consideration of toxin-induced states. Persistent hyperthermia and acidosis in a weight lifter should trigger concern for DNP abuse. The presence of yellow staining virtually clinches the diagnosis.52

Management and Disposition

Initial treatment is directed toward control of body temperature; treatment of acidosis; protecting the kidneys, brain, and liver from hyperthermic damage; and providing the basic substrates for excessive metabolic activity—oxygen, glucose, and water.52 If the chemical exposure is known or recognized, early decontamination of affected sites is important. Therapy should be directed toward prevention or minimization of the associated complications discussed previously. Patients with mild toxicity can usually be stabilized after a few hours and discharged from the emergency department. Patients with significant organ system injury or a high likelihood of complications, such as prolonged or recurrent seizures, significant alteration of consciousness, and rhabdomyolysis, require admission, usually to the intensive care unit.

CHLOROPHENOXY COMPOUNDS

The chlorophenoxy pesticides were developed in the early 1940s and hailed as a selective herbicide particularly effective against broadleaf weeds. This class of herbicide developed a special notoriety during the Vietnam War as Agent Orange, a defoliant used in aerial spraying. Agent Orange consisted of a mixture of 2,4-dichlorophenoxyacetic acid (2,4-D) and 2,4,5-trichlorophenoxyacetic acid (2,4,5-T). 2,4,5-T is almost always contaminated with isomers of tetrachlorodibenzo dioxin. This concern regarding dioxin exposure has led to the extensive medical investigations of Vietnam veterans and severe restrictions on the production and use of 2,4,5-T.54 Because of the relative safety and broadleaf selectivity of 2,4-D, however, most home gardeners have at least one chlorophenoxy compound on a shelf in their garages, and some old cans may contain 2,4,5-T or a mixture of both compounds.

Principles of Disease

Chlorophenoxy compounds may be absorbed through the skin, GI tract, and respiratory tract, but almost all significant poisonings occur as a result of accidental or intentional ingestion. The lipid solubility of these compounds is low, and excretion is fairly rapid, so cumulative toxicity from repeated exposures does not occur.55

Although skeletal muscle is the target organ for chlorophenoxy herbicides, the exact mechanism is obscure.40,56 Depending on severity, muscular abnormalities may range from generalized muscle weakness to acute rhabdomyolysis. Higher doses may also uncouple oxidative phosphorylation and cause a hypermetabolic state similar to that seen with the substituted phenols.40

Clinical Features

Similar to most organic pesticides in an organic solvent, the chlorophenoxy herbicides may produce mild, nonspecific dermal and GI irritation with nausea, vomiting, and GI distress. Large exposures are likely to cause systemic symptoms ranging from diffuse myotonia and muscle fasciculations progressing to rhabdomyolysis, hyperthermia, and a hypermetabolic state with metabolic acidosis.57

Diagnostic Strategies

There are no specific tests for the detection of the chlorophenoxy compounds. Laboratory evaluation should be aimed at evaluating skeletal muscle injury and its complications. Severely poisoned patients require generalized organ system evaluation, including hepatic and renal function, because of the effects of rhabdomyolysis and hyperthermia.

Differential Considerations

Differential diagnostic possibilities include other causes of acute myopathy. The manifestation of chlorophenoxy compound toxicity is extremely rare, however, and without a definite history or strong suspicion of exposure, other explanations for acute myopathy should be pursued.

Management and Disposition

Treatment consists of initial skin decontamination, activated charcoal or gastric lavage with early presentation, and basic supportive care. Serious toxic effects develop within 4 to 6 hours after ingestion, and treatment can be directed toward the specific problems of muscle weakness, airway and ventilatory support, and rhabdomyolysis. Treatment of hyperthermia and acidosis has been discussed previously.

Asymptomatic or minimally symptomatic patients may be discharged with reassurance after 4 to 6 hours of observation. Patients with significant toxicity should be admitted for close observation and monitoring.

BIPYRIDYL COMPOUNDS

The bipyridyl (also called dipyrilidyl) compounds, paraquat and diquat, were first investigated in the late 1950s and early 1960s. They are extremely effective contact herbicides that are rapidly inactivated by the surrounding soil in the event of overspraying. Paraquat is activated when exposed to sunlight, which led to its use as the herbicide of choice after aerial spraying of marijuana by the U.S. and Mexican governments. After spraying, however, growers simply would harvest the crops before the plants were exposed to enough sunlight to damage the plants, resulting in an apparently healthy harvest but one contaminated with paraquat. The burning of marijuana pyrolyzes paraquat into a nontoxic form, a fact that was lost in the warning messages dispensed by the government at that time.58

Principles of Disease

Of the two bipyridyl compounds in use, paraquat is the most clinically significant in terms of number of cases and toxic effects. Paraquat use is tightly regulated in the United States but is widespread throughout the world. Diquat is less regulated in the United States and is included in some formulations of Roundup. Paraquat is absorbed through the skin, GI tract, and respiratory tract. Almost all fatal exposures have resulted from the ingestion of paraquat, although a few case reports have involved extensive skin contamination.59 Toxicity has occurred, but no fatal cases have been reported from inhalation of paraquat vapor or aerosols. Diquat is poorly
PART IV
Environmental and Toxicology / Section Two • Toxicology

Toxicology

The effects of the poisoning. Studies other than evaluation of caustic GI injury and pulmonary injury usually occurs over 1 to 3 weeks, although the clinical course varies considerably with severity of poisoning, involvement of other organ systems, and underlying medical problems. This is not a factor in the emergency department, and the delayed pulmonary injury is not discussed here. In contrast to paraquat, diquat usually spares the lungs but produces similar toxicity in all other organ systems.

Diagnostic Strategies

Paraquat is measurable in the blood, and the nomogram provides a fairly accurate prognosis. The assay is not readily available in the United States, and in most cases, by the time the results are obtained, nothing more can be done to change the eventual outcome. There is a qualitative bedside test that uses the reduction of paraquat or diquat in alkalinized urine by sodium dithionite, but the reagent frequently is not available. Studies other than evaluation of caustic GI injury and pulmonary and renal damage should be directed toward secondary effects of the poisoning.

Differential Considerations

A person with acute paraquat or diquat ingestion is likely to present with the initial complaint of an acute corrosive injury; the differential diagnosis should encompass all corrosive agents. Successful therapeutic intervention for paraquat toxicity is extremely time dependent, and patient outcome depends on the history. Any patient who has evidence of pulmonary or other organ injury caused by paraquat exposure is probably already beyond recovery.

Management and Disposition

There are no studies comparing various treatment strategies, but the key to successful treatment of an acute paraquat exposure likely depends on early decontamination measures to limit absorption. Thorough skin cleansing is obvious and straightforward in dermal exposures. Careful gastric lavage and administration of activated charcoal may be lifesaving, but these measures should be undertaken in consultation with a poison center and may even be hazardous in the context of a corrosive ingestion. Early endoscopy and surgical intervention may be necessary if there is evidence of esophageal perforation and mediastinitis. Although Fuller’s earth and bentonite are recommended as adsorbents in paraquat ingestions, activated charcoal is much more readily available in the United States and has equal, if not greater, efficacy.

Although controversial, many toxicologists recommend rapid initiation of charcoal hemoperfusion to rapidly lower plasma paraquat levels and to limit pulmonary and other organ system uptake of paraquat. Many also recommend serial and combined hemoperfusion and hemodialysis, particularly during the first 24 hours after exposure. There are multiple suggested treatment protocols for paraquat, such as N-acetyl-cysteine, low fraction of inspired oxygen, and cytoprotective agents such as amifostine, but no single therapy has proven consistently successful.

Patients with any significant dermal paraquat exposure and all patients with ingested paraquat require hospitalization and consideration of enhanced elimination therapy. These patients should be observed and treated expectantly until paraquat levels are reported to be nonexistent or nontoxic.

PYRETHRINS AND PYRETHROIDS

Pyrethrins are naturally occurring insecticides of the yellow Chrysanthemum cinerariifolium and Tanacetum cinerariifolium and are among the oldest known insecticides, first used in the 1800s. Extracts of the dried flowers contain the active compound pyrethrum, which contains six naturally occurring pyrethrins. In addition, numerous synthetic derivatives, pyrethroids, have been produced and have greater chemical stability than the natural pyrethrins. Type II pyrethroids contain a cyano substituent and are among the more toxic formulations of this class. These present a potential danger to humans, but type II pyrethroids are generally less toxic than many of the other classes already discussed and are being used more commonly.

Principles of Disease

Because pyrethrins and pyrethroids are most commonly aerosolized, inhalation is the most likely route of exposure. The patient may not be aware of an exposure because pyrethrin and pyrethroid aerosols are used frequently as automated insect sprays in public areas, such as in airplanes. In these situations, concentrations rarely reach levels likely to produce symptoms in any but the most sensitized patient. Occasional ingestions have been reported, and significant toxicity is possible via this route. Systemic absorption via the dermal route is unlikely, but topical effects are possible. Most pyrethrins and pyrethroids are rapidly metabolized and deactivated in human exposure, so cumulative toxicity is not a problem. Piperonyl butoxide, which is added as an insect “knockdown” agent, may increase the toxicity of the pyrethrum derivatives.

Pyrethrins and pyrethroids have a variety of effects in humans and other mammals. Clinically, the naturally
occurring pyrethrins can cause sensitization and allergic phenomena. This property does not occur with the synthetic pyrethroids. Both classes are associated with sodium channel blockade, slowing the rate of activation of the sodium channel and extending the time during which the channel is open. In addition, both classes affect GABA receptors, inhibiting chloride channel function. Less significant effects include potentiation of nicotinic cholinergic neurotransmission, enhancement of norepinephrine release, and inhibition of calcium adenosine triphosphatase interference with sodium-calcium exchange across membranes.\(^\text{71,72}\)

**Clinical Features**

Allergic manifestations, including potentially life-threatening events, may occur after acute inhalation or dermal exposure. Inhalation exposure often occurs with the use of a pyrethrin-based aerosol in an enclosed, poorly ventilated space. Local effects include lacrimation, rhinitis, rhinorrhea, sneezing, throat irritation, and pharyngeal and laryngeal edema. Lower respiratory effects include cough, shortness of breath, chest pain, and wheezing. Skin rashes, consistent with a contact or allergic dermatitis, and photosensitivity may contribute to the dermatologic picture. There is potential for allergic cross-reactivity in patients who are allergic to ragweed.

Sodium channel-mediated and GABA-A-mediated chloride channel effects mediate neurologic signs and symptoms. Facial paresthesias have been reported, and seizures occur with massive ingestions.\(^\text{71,72}\) Nonspecific symptoms, such as headache, fatigue, dizziness, and weakness, have been reported.

**Diagnostic Strategies**

No laboratory tests are available to measure pyrethrins or pyrethroids in a clinical setting.

**Differential Considerations**

The differential diagnosis of the signs and symptoms of pyrethrin or pyrethroid toxicity includes the usual causes of bronchospasm and seizures and other acute neurologic complications.

**Management and Disposition**

Decontamination, including removal from a contaminated environment or washing, should be the first step. Definitive treatment is supportive and directed at the respiratory and neurologic complications.

Disposition of a patient with exposure to pyrethrins depends on the severity of the underlying complications. If discharge from the emergency department is anticipated, the patient should be counseled with regard to the possibility of recurrent allergic phenomena on reexposure.

## GLYPHOSATE

Glyphosate (Roundup) was introduced as a broad-spectrum nonselective herbicide in 1971 by the Monsanto Agricultural Company. It is the isopropyl ammonium salt of a noncholinesterase-inhibiting organophosphate herbicide. It is sold mixed with the surfactant polyoxyethylene amine (POEA). Because it is effective on broadleaf weeds and does not undergo photodecomposition, it is popular in the home market. Newer formulations of Roundup may contain diquat.

### Principles of Disease

Glyphosate is poorly absorbed through the skin so that most exposures result from ingestion. The concentrated solution is extremely irritating, and patients may vomit with subsequent aspiration. The concentrated solution is provided as 41% glyphosate in 15% POEA. The directions state that it should be diluted to a 1% glyphosate solution.

Glyphosate is toxic to plants by inhibition of the enzyme 5-enolpyruvylshikimate-3-phosphatase-synthetase in the shikimic acid metabolic pathway. After application of glyphosate on the leaves, it is transported to the roots, where the enzyme is active. Humans lack this enzyme and are unlikely to develop toxicity. Reported toxicity is believed to result largely from the surfactant POEA and may reflect the direct corrosive effect from the amine salt, or it may uncouple oxidative phosphorylation.\(^\text{73}\)

### Clinical Features

Most ingestions of the dilute solution cause only minimal symptoms, including GI distress. Patients ingesting large volumes of dilute solutions or moderate volumes of concentrated solutions complain of sore throat, nausea, abdominal pain, and fever. They may develop vomiting, diarrhea, respiratory distress, noncardiogenic pulmonary edema, dysrhythmias, shock, coma, and renal failure. Acidosis reflects poor tissue perfusion and cardiovascular compromise.\(^\text{73}\) Negative prognostic indicators include shock, acidosis, and persistent hyperkalemia.\(^\text{73}\)

### Diagnostic Strategies

The critical element in diagnosis is history of ingestion. Laboratory analysis may demonstrate an anion gap metabolic acidosis, hypoxemia, and hyperkalemia. Elevated transaminases may occur in 30% of ill patients, and signs of renal failure may develop in persistent shock states. The electrocardiogram may show ventricular dysrhythmias and secondary signs of hypoxemia.\(^\text{73}\)

### Differential Diagnosis

The differential diagnosis includes most corrosive ingestions and causes of shock. The findings of hyperkalemia and metabolic acidosis may suggest hydrofluoric acid ingestions. A normal ionized calcium level may help rule out hydrofluoric acid exposure. Any cause of aspiration should also be considered. The history is the most useful factor in the differential diagnosis.

### Management and Disposition

Treatment is supportive. The patient may require positive-pressure ventilation to overcome the noncardiogenic pulmonary edema. POEA may also be a direct cardiac depressant; inotropic agents can be useful. Hyperkalemia should be treated in the usual manner with fluids, medications to shift potassium into the cell (e.g., bicarbonate, calcium, and beta-adrenergic agonists), and kayexalate. If there is an indication of significant corrosive ingestion, early endoscopy with placement of stent, high-dose steroids, and laparotomy may be considered. Asymptomatic patients with small ingestions of dilute substances may be observed for 6 hours and discharged. Patients with complaints consistent with corrosive ingestions require admission and GI evaluation. Any patient with pulmonary complaints requires admission and intensive supportive care.
**DEET**

\( \text{N,N-diethyl-\textit{N}-toluamide or N,N-diethyl-3-methylbenzamide (DEET)} \) is not a pesticide but an insect repellent. It is the most widely used chemical insect repellent in the United States. DEET was developed by scientists at the U.S. Department of Agriculture in 1946, patented by the U.S. Army soon thereafter, and released to the general public in 1957. With the prevalence of Lyme disease and other concerning arthropod-borne diseases, the use of DEET has increased greatly. Formulations containing DEET range from 5 to 100%. The U.S. Army routinely used 75% solutions until 1987 but now uses a 35% time-release, polymer-based formulation. The American Academy of Pediatrics (AAP) recommends 30% as the maximum concentration that should be used in infants and children. The AAP does not recommend use of DEET in infants younger than 2 months.75

**Principles of Disease**

DEET is lipophilic and can be absorbed through the skin. Skin absorption and toxicity increase with repeated applications, increased ambient temperatures, sweating, and abraded, thin skin. Ingestion may lead to toxicity.76 DEET primarily affects the central nervous system. Its mechanism of action is unknown. It may sensitize the skin and cause allergic reactions.

**Clinical Features**

Prolonged skin contact may lead to contact dermatitis, and prolonged contact with high concentrations has led to skin blisters. Patients who have ingested DEET or have repeated skin applications in a hot enclosed environment that enhances absorption have developed liver function test abnormalities and neurologic findings, including encephalopathy, seizures, movement disorders, and coma.76 Most exposures to DEET result in no, or minimal, toxicity and should not preclude its use in susceptible populations in which significant arthropod-borne diseases are prevalent.77

**Diagnostic Strategies**

Exposure history is central to the diagnosis. Although DEET can be detected in urine, most laboratories are not able to do this testing during the acute toxicity phase. An electroencephalogram may be useful in a patient with coma or encephalopathy and seizures.

**Differential Diagnosis**

The differential diagnosis includes conditions that may cause encephalopathy, seizures, and movement disorders. Such conditions include drug intoxication, infectious causes, drug interactions, and structural defects.

**Management and Disposition**

Treatment is supportive. If DEET exposure is suspected, the skin should be thoroughly decontaminated. Oils or lipophilic agents should be avoided because they enhance skin absorption. After DEET ingestion, milk products and oil-containing foods should be avoided until the GI tract has eliminated the offending agent. Seizures should be treated with benzodiazepines.

Asymptomatic patients who have ingested DEET-containing repellents should be observed for 4 to 6 hours. Patients who develop neurologic symptoms should be admitted and observed.

---

**KEY CONCEPTS**

- All patients exposed to cholinesterase inhibitors should have skin decontamination. Emergency department personnel need to be protected during this process.
- Morbidity in cholinesterase inhibitor exposure results from early airway compromise secondary to copious secretions, status epilepticus, and late respiratory failure.
- Cholinesterase inhibitor exposure may include bradycardia or tachycardia, hypertension or hypotension, and miosis or mydriasis.
- The clinical endpoint for atropine administration is drying of airway secretions.
- Pralidoxime should be given to all organophosphorus-poisoned patients who require atropine regardless of time since exposure.
- With chlorinated hydrocarbon exposures, skin decontamination with protection of personnel is indicated.
- In chlorinated hydrocarbon exposures, catecholamine administration is avoided.
- Supportive care, temperature control, and seizure control are important.
- Rapid cooling and substrate provision (glucose) are the two most important therapies in substituted phenol toxicity.
- Diagnosis of chlorophenoxy compound toxicity depends on a history of accidental or deliberate ingestion.
- Rapid GI decontamination may be indicated in paraquat and diquat ingestions despite the corrosive injury.
- The predominant form of pyrethrin and pyrethroid toxicity is allergic.
- Small ingestions of dilute glyphosate solutions are GI irritants. Large or concentrated ingestions may cause acidosis, hyperkalemia, and noncardiogenic pulmonary edema.
- DEET should not be applied over abraded or raw skin.
- DEET applications to children should be restricted to 30% solutions, should not be used under occlusive clothing, and should be washed off completely between applications.

Botanicals such as plants, herbal products, and mushrooms have a long-standing and important place in medical history. Their use as therapeutic agents has been documented in the earliest of medical writings. The extraction of alkaloids from the opium poppy in the 1800s was a forerunner of modern pharmacology. The general public increasingly is using herbal products for medicinal purposes. Despite the tremendous growth in popularity of herbal products, data on herbal efficacy and toxicity are limited. This chapter does not focus on the medicinal use of natural products, but rather the toxicology related to their exposure or utility.

Epidemiology
Although plants, mushrooms, and herbal products all are derived naturally, they have different exposure patterns and epidemiology.

Unintentional Childhood Exposure
Unintentional childhood exposure occurs most commonly with plants. Approximately 5% of all poison center calls involve plants. Of these, about 75% involve children younger than 6 years. Most of these cases involve household plants with a limited amount of plant or toxin ingested, resulting in little or no toxicity.1

Misidentification of Botanical
Natural plant and mushroom gathering for personal ingestion is a popular activity. Mistakes while foraging commonly occur, with the potential for serious toxicity and death. In contrast to unintentional childhood exposures, foraging accidents usually involve adults and plants or mushrooms and are associated with a much larger toxin burden because a larger quantity of the botanical is ingested. Another type of botanical misidentification occurs with herbal products when plants used for herbal manufacture are misidentified by the manufacturer and incorrectly packaged and marketed.

Plants as Drugs of Abuse
Many plants and mushrooms are abused for their mind-altering potential, including hallucinogenic mushrooms, peyote, kava kava, and anticholinergic plants, such as jimsonweed.2,3

Identification of the botanical in question is most useful, but most patients and medical professionals do not have any knowledge of botany or plant identification. The name of the plant or mushroom is often confusing because the scientific name is not typically known, and common names often overlap. Most emergency department personnel cannot identify common plants, such as mistletoe, holly berries, philodendron, and others. Several resources may be helpful, including plant atlases, CD-ROM plant databases, a local botanical expert, botanical garden personnel, or a poison center. Alternatively, digital photography of the plant or mushroom in question can be quickly e-mailed to a local expert to aid in identification.4 With herbal products, the product name or herbal plant may be known. Because of the limited Food and Drug Administration (FDA) regulation, however, the purported herb might have been harvested from the wrong plant or contaminated with other toxic material.

Plants
Among more than 100,000 plant exposures reported to U.S. poison centers annually, most plant exposures occur in children (<6 years old), involve household plants, and 80% of exposed individuals never develop any toxicologic symptoms. Hospitalization for plant poisoning is rare, with fatalities occurring in less than one in a million exposures. Of thousands of different plant species, only a few are dangerously toxic.5,6 More detailed discussion of specific plants focuses on plants that are most poisonous and most commonly implicated in human exposures.

Abrus precatorius
_Abrus precatorius_ (Fig. 162-1), known as the jequirity pea, rosary pea, prayer bean, Seminole bean, Indian bean, and crab’s eye, contains the toxin abrin, which affects protein synthesis, leading to cell death. The toxin is found in highest concentration in the seeds, which are used in jewelry or decoration. Because of their attractiveness, the seeds are often ingested by children. The hard, shiny coat causes most seeds to pass through the gastrointestinal tract without being digested. If the seeds are chewed or do not pass through the bowel rapidly and become digested, abrin is released; nausea, vomiting, and abdominal pain can be severe, and fluid and electrolyte balance is disturbed.7,8 Systemic absorption of the
toxin is limited because the protein is enzymatically digested. Rare parenteral exposure of small amounts is associated with severe toxicity and possible death. Treatment is supportive, with attention to fluid rehydration and electrolytes. Asymptomatic patients should be treated with activated charcoal, and whole-bowel irrigation may be helpful in moving numerous seeds more rapidly through the gastrointestinal tract.

**Brassaia**

The *Brassaia* is a popular indoor plant known as schefflera, umbrella tree, Australian umbrella tree, dwarf schefflera, rubber tree, and starleaf. This plant contains calcium oxalate crystals, which can cause mouth pain, but most ingestions cause mild or no symptoms.

**Capsicum annum**

*Capsicum annum* includes many types of peppers (e.g., chili pepper, red pepper, bell pepper) and contains the active toxin capsaicin. This alkaloid releases and depletes selected nerve terminals of substance P, causing a severe local inflammatory response, manifested by swelling, fluid exudation, and pain, which resolves rapidly as capsaicin depletes substance P. Capsaicin is not absorbed well through intact skin, but symptoms occur rarely, with prolonged and intense exposure. Ingestions often cause gastrointestinal symptoms depending on the amount of toxin exposure. Most capsaicin exposures involve a pepper spray product, causing chemical conjunctivitis. Keratitis can occur and is assessed with fluorescein. Treatment consists of local irrigation and anesthetics. Despite their often dramatic appearance, cases resolve rapidly over several hours without sequelae. Inhalation of capsaicin-containing powders is less common but can cause severe pulmonary edema, potential acute respiratory distress syndrome, and death. Treatment is supportive, but extracorporeal membrane oxygenation may be useful for acute respiratory distress syndrome.

**Cicuta maculata**

*Cicuta maculata* (Fig. 162-2), commonly known as water hemlock, contains the potent neurotoxin cicutoxin. Deaths from water hemlock are among the most commonly reported plant fatalities reported in the United States. Water hemlock has small white flowers at the ends of umbrella-like stems. They resemble *Daucus carota* (Queen Anne’s lace) and *Heracleum lanatum* (cow parsnip). Mistaking water hemlock for one of these edible plants has been a common cause for exposure. Ingestion of any part of the plant can lead to nausea, vomiting, and abdominal cramping. Severe toxicity is manifested by seizures, occurring within the first hour, which often are intractable and are a common cause of death. The toxic mechanism may be due to γ-aminobutyric acid (GABA) receptor antagonism. Fatality rates may be as high as 70%. Aggressive supportive care is necessary, and asymptomatic suspected exposures should be treated aggressively with gastric lavage and activated charcoal. Patients often arrive in the emergency department with active seizures and should receive benzodiazepines and barbiturates.

**Conium maculatum**

*Conium maculatum* (Fig. 162-3), or poison hemlock, was purported to be used in the execution of Socrates. It is mistaken for several edible plants, such as *Daucus carota* (Queen Anne’s lace) and *Heracleum lanatum* (cow parsnip). Poison hemlock contains the toxin coniine, which is similar to nicotine in structure and toxicity. The clinical picture and management resemble tobacco poisoning (see section on *Nicotiana tabacum*).

**Datura stramonium**

*Datura stramonium* (jimsonweed) (Fig. 162-4) is one of numerous plants with alkaloids that have anticholinergic effects (see Chapter 148). The fruit is spiny and when opened contains 50 to 100 black seeds. All parts (including the seeds) contain the toxins atropine, hyoscyamine, and scopolamine, which are all potent anticholinergic agents. One hundred seeds approximate 6 mg of atropine. Exposures are most commonly a result...
of abuse for hallucinogenic effects, usually by smoking dried leaves or ingesting the seeds. The clinical picture is that of anticholinergic toxidrome. The symptoms can be prolonged several days if the overdose is due to ingestion of seeds. It is unclear if activated charcoal and gastric emptying measures are effective at decreasing the course of toxicity. Physostigmine reverses the clinical symptoms. Anticholinergic symptoms typically return as the effects of physostigmine wear off (see Chapter 148).

**Dieffenbachia**

*Dieffenbachia* (Fig. 162-5) has more than 30 different common names, including dumb cane, mother-in-law’s tongue, dumb plant, and tuft root. Some of these names refer to the inability to talk that can occur after biting into parts of this plant. Typically the mucous membranes of the mouth are affected immediately with severe pain, swelling, and the sensation of biting into glass. Most cases are limited to the mucous membranes of the oropharynx. Rare cases of airway compromise have been reported. The local effects are due to calcium oxalate crystals, packaged into bundles called raphides, which are found in cellular structures called idioblasts. These idioblasts also contain proteolytic enzymes that are ejected out of the idioblasts with the oxalate crystals when plant parts are chewed. Because of the immediate pain, further exposure typically is limited. Treatment is aimed at pain relief and local supportive measures, typified by feeding a symptomatic infant ice cream.

**Epipremnium aureum**

*Epipremnium aureum* is a common household plant also known as pothos ivy, devil’s ivy, hunter’s robe, and golden pothos. Toxicity is due to calcium oxalate crystals, the same toxin found in the *Dieffenbachia*, and the toxicity and treatment are similar.

**Eucalyptus**

*Eucalyptus* plants have common names, such as the silver dollar, lemon-scented gum, cider gum, and blue gum. These plants are not toxic but are implicated in frequent plant exposures. The plants are used, however, to produce concentrated (approximately 70%) eucalyptus oil. Ingestion of small amounts (1–3 mL) has been reported to cause severe toxicity. The predominant symptoms are neurologic, including mental status alteration, headache, ataxia, and seizures. Treatment for severe toxicity is supportive.

**Euphorbia pulcherrima**

*Euphorbia pulcherrima* (poinsettia) is a popular ornamental plant that is frequently implicated in plant exposures. It has a false reputation for being extremely poisonous. Ingestions are benign or cause minimal toxicity. However, contact dermatitis is relatively common with skin exposure.

**Ilex**

*Ilex* (holly) contains more than 400 different species and is frequently implicated in plant exposures. The plant’s red and black berries are attractive to children and contain numerous toxins that are potent gastrointestinal irritants. Symptoms include nausea, vomiting, abdominal cramping, and diarrhea.

**Nerium oleander**

*Nerium oleander* (Fig. 162-6), or oleander, is one of many plants that contain toxic cardiac glycosides structurally similar to...
digoxin. Ingestion of several leaves is unlikely to cause serious symptoms.\textsuperscript{29,30} Large exposures from suicide attempts or misidentification of plants used for teas or herbal products can lead to severe toxicity or death. The cardiac glycosides are potent sodium-potassium adenosine triphosphatase inhibitors, and the symptoms they cause are similar to those of digoxin poisoning (see Chapter 150). Measurement of an abnormal digoxin level is only qualitative proof of exposure because the serum digoxin test can falsely measure nondigoxin cardiac glycosides. Conversely, a negative digoxin measurement does not rule out exposure because the level of cardiac glycoside cross-reactivity varies.\textsuperscript{28} Treatment for suspected oleander ingestion includes multidose activated charcoal and digoxin-specific Fab antibodies (see Chapter 150)\textsuperscript{29–33}; however, larger doses of Fab fragments generally are needed than for comparable digoxin poisonings. Initial empirical doses of 10 to 20 vials of digoxin-specific Fab fragments have been suggested.\textsuperscript{32}

**Nicotiana tabacum**

*Nicotiana tabacum* is widely grown in the southeastern United States as a source for cigarette and cigar tobacco. Several *Nicotiana* species contain nicotine as their major toxin, which activates and subsequently blocks acetylcholine receptors in the central nervous system (CNS) and peripheral autonomic nervous system. Most exposures are ingestion of cigarettes or cigars by young children. Dermal exposure to workers harvesting plants and ingestion of wild plants mistaken for edible plants also have led to poisoning.\textsuperscript{34} The ingestion of one to two cigarettes has the potential to cause moderate poisoning in children. Most children ingesting cigarettes do not manifest toxicity. Patients not experiencing nausea and vomiting do not seem to be at risk for more severe toxicity.\textsuperscript{35} Dermal exposure in tobacco workers has been called *green tobacco sickness.*\textsuperscript{36,37} Nicotine is absorbed through the skin and occurs most severely when the skin or plant is wet. Exposure can be avoided by using proper protective equipment.

Symptoms begin shortly after absorption. Nausea, vomiting, salivation, lacrimation, diarrhea, hypertension, tachycardia, diaphoresis, agitation, and fasciculation are seen initially. More severe toxicity is manifested by seizures, respiratory depression (muscle weakness), and hyperthermia.\textsuperscript{38} Treatment for ingestion is aimed initially at limiting absorption with activated charcoal. Other treatments are supportive in nature because no specific antidote for nicotine is available. Benzodiazepines are used for seizures and agitation. If severe salivation and lacrimation occur, atropine in 1-mg doses may be repeated until symptoms improve.

**Phytolacca americana**

Found in the eastern United States, *Phytolacca americana* (Fig. 162-7) is commonly known as pokeweed, poke, pokeberry, inkberry, scoke, American cancer, garget, phytolacca, and pigeonberry. Although the plant is poisonous, it can be detoxified by boiling it in water twice before use in salads or other recipes. Toxicity is seen when the plant is inadequately detoxified, or raw parts of the plant are eaten.\textsuperscript{39} Symptoms begin shortly after ingestion and include severe nausea, vomiting, abdominal cramping, and diarrhea. Treatment is supportive.

**Pyracantha**

*Pyracantha*, commonly known as the firethorn, has small red, orange, or yellow fruit attractive to and commonly ingested by children. The plant is not toxic, but the thorny parts can penetrate skin deeply and are difficult to remove.

**Rhododendron**

*Rhododendron* includes more than 1000 species of azaleas and rhododendrons, including mountain laurel, dwarf laurel, rose bay, western Labrador tea, and Japanese pieris. Numerous structurally related toxins (diterpene polyalcohols) have been identified from these plants, including grayanotoxin, rhodojaponin, asebotoxin, and others.\textsuperscript{40,41} These toxins bind to sodium channels and increase permeability (sodium channel openers), causing cardiovascular (e.g., bradycardia and hypotension) and gastrointestinal (e.g., nausea, vomiting, and abdominal pain) effects. Although ingestion of a few leaves is unlikely to cause
symptoms, larger exposures can cause severe toxicity. Additionally, these plant toxins can be concentrated in honey. Large honey ingestions, “mad honey,” can also lead to toxicity. However, no deaths have been reported. Treatment is supportive; atropine and cardiac pacing have been used for bradycardia in rare cases. Sodium channel-blocking agents, such as quinidine and procainamide, may have theoretical value in severe cases, although their efficacy is unclear.

**Spapihyllum**

*Spapihyllum* includes the peace lily, Mauna Loa, white anthurium, and snowflower. These plants contain calcium oxalates and have similar toxicity and treatment as *Dieffenbachia*.

**Taxus**

*Taxus* (yew trees) (Fig. 162-8) have a hard seed surrounded by a fleshy red cup (the aril). The aril portion is not poisonous, and the seed has a hard coat that limits toxin release in the gastrointestinal tract so that most ingestions are nontoxic. If the seed is masticated or leaves are ingested, cardiac (e.g., bradycardia and hypotension) and gastrointestinal symptoms (e.g., nausea, vomiting, and abdominal pain) may occur. Deaths from this plant have been reported, usually in the setting of a suicide and secondary to cardiac manifestations.

### HERBAL MEDICINES

Herbal products have gained an extraordinary amount of popularity over the past several decades. Although the highest usage is among immigrants and patients with difficult-to-treat diseases, such as advanced cancer and acquired immunodeficiency syndrome, these products are used by 30% of the general population. Consumers often perceive herbal products as “natural” and thus “safer” and “harmless.” Additionally, herbal products are widely marketed as such, especially on the Internet. One study of pregnant patients documented 45% herbal medicine usage during some point of their pregnancy.

**Digitalis lanata**, 1997

An herbal dietary supplement used for “internal cleansing” contained 14 herbal ingredients. Two patients developed complete heart block because one of the herbal ingredients, plantain, contained *Digitalis lanata* (a cardiac glycoside-containing plant).

**Dandelion Salad**, 2004

Dandelion is a commonly ingested herb used as an appetite stimulant and diuretic. Many users grow and harvest their own plants. A 53-year-old woman who had ingested some homegrown dandelion developed persistent nausea, vomiting, and bradycardia with a heart rate between 30 and 40 beats per minute. Her bradycardia persisted for several days and had associated syncope. Her diagnosis was unclear until it was discovered that she had mistakenly harvested and ingested foxglove instead of dandelion.

**Paraguay Tea**, 1994

The South American herbal tea Paraguay tea is made from *Ilex paraguariensis*, used for urinary tract infections, cardiac insufficiency, and “lack of stamina.” In 1994, several individuals had anticholinergic poisoning from Paraguay tea, after the manufacturer had purchased and mistakenly used other plant materials containing the belladonna alkaloids atropine, scopolamine, and hyoscymine directly from farmers before packaging.

**Herbal Slimming Regimen**, 1992

During the early 1990s, the Chinese herbs *Stephania tetrandra* and *Magnolia officinalis* were used for weight loss in Belgium. Many cases of interstitial fibrosis of the kidney occurred with the use of these herbal compounds. Analysis found that *S. tetrandra*, which was substituted for *Aristolochia fangchi*, contains the nephrotoxin aristolochic acid.

**Misidentification of Herbal Plants**

Incorrect plant identification and subsequent use in the production of herbal products have occurred on numerous occasions, leading to epidemic exposures with tragic outcomes. The following examples illustrate this problem.

**Figure 162-8. Taxus (yew). (Courtesy of Steven Setzer.)**

### Contamination with Nonherbal Toxic Material

Contamination with nonherbal toxic material as a mechanism of herbal toxicity may be due to contamination of the products at the time of manufacture or consumer fraud. Because of the limited FDA regulation of herbal manufacturers, one of the major risks of herbal usage is the use of a product contaminated with a toxic substance. A study of Asian herbal patent medications sold in California found that 32% of these products were contaminated with heavy metals or undeclared pharmaceuticals. Contamination with nonherbal toxic material as a mechanism of herbal toxicity may be due to contamination of the products at the time of manufacture or consumer fraud. Because of the limited FDA regulation of herbal manufacturers, one of the major risks of herbal usage is the use of a product contaminated with a toxic substance. A study of Asian herbal patent medications sold in California found that 32% of these products were contaminated with heavy metals or undeclared pharmaceuticals. Lead, mercury, arsenic, cadmium, aluminum, tin, zinc, and copper all have been found in herbal products. The most common undeclared pharmaceuticals include ephedrine, chlorpheniramine, methyltestosterone, and phenacetin. It is not clear why heavy metals are found in herbal products. Metal shavings have been added to herbal preparations to

1. **ACE, angiotensin-converting enzyme; INR, international normalized ratio; MAO, monoamine oxidase.**
2. **Heavy metals** are found in herbal products. The most common undeclared pharmaceuticals include ephedrine, chlorpheniramine, methyltestosterone, and phenacetin. It is not clear why heavy metals are found in herbal products. Metal shavings have been added to herbal preparations to
increase selling price when the herbals are sold by weight. Some herbal products use the metal as an active ingredient with a purported medicinal benefit (e.g., lead in azarcon or mercury in cinnabar). Other cases involve contamination with the metals during the manufacturing process.\textsuperscript{71–73} Consumer fraud in the herbal industry has been well documented on numerous occasions. Typically an FDA-controlled pharmaceutical product is mixed in with an herbal product, or the label did not list the pharmaceutical agent.

Chuifong Toukuwan was an herbal preparation that was associated with several cases of agranulocytosis. Analysis revealed that it contained phenylbutazone, indomethacin, and aminopyrine.\textsuperscript{74} Gan Mao Tong was an herbal product found to contain phenylbutazone, causing aplastic anemia.\textsuperscript{75} An undefined herbal preparation that was used “to avoid taking other medicine” was found to contain triamcinolone. A patient using the product for more than 1 year had several manifestations of steroid excess: thoracic compression fractures, proximal muscle weakness, and osteoporosis.\textsuperscript{76} Tung shueh was an herbal product that was found to contain mefenamic acid and diazepam, causing gastrointestinal bleeding and acute interstitial nephritis.\textsuperscript{77} Another herbal product was found to contain mefenamic acid, which caused acute renal failure necessitating hemodialysis. Dr. Tong Shap Yee’s asthma pills were found to contain theophylline.\textsuperscript{78} Leng Pui Kee herbal cough remedy was found to contain bromhexine.\textsuperscript{78}

**Direct Toxicity of Herbals and Herbal-Drug Interactions**

Some herbal preparations can cause allergic reactions ranging from contact dermatitis to anaphylactic shock (Box 162-1).\textsuperscript{79,80} Other herbal products are associated with uncommon idiosyncratic reactions, particularly hepatic toxicity (see Table 162-1). Herbal products are often taken in overdose. Not controlled by a prescription system, herbal medicines are seen as natural and safe so that “if one is good, then two or three is better.” Direct toxicity is often due to this overdose. Herbals associated with specific toxicities and side effects are listed in Table 162-1.\textsuperscript{81–90}

Concurrent herbal and pharmaceutical use is common and can cause drug interactions. Of U.S. adults, 18\% who take prescription medications also use an herbal or mineral supplement, and 60\% who use alternative therapies are unlikely to report this to their physicians.\textsuperscript{91} Individuals often do not consider that herbs can potentially interact with conventional medicines, and serious drug reactions associated with an herbal product are less likely to be reported than reactions that occur with a conventional medicine. Common herbal-drug interactions are listed in Table 162-2.\textsuperscript{58,92,93}

### MUSHROOMS

U.S. poison center data estimate that five exposures take place for every 100,000 population per year. These exposures occur in three types of situations: (1) accidental ingestion of wild mushrooms by young children playing outdoors (which usually results in a small exposure), (2) mistaken selection of poisonous mushrooms while foraging for edible wild mushrooms intended for a meal (which leads to a larger toxin exposure and most of the severe cases of mushroom poisoning, including deaths), and (3) abuse of certain mushrooms for their mind-altering potential.\textsuperscript{2,3} Mushrooms of abuse typically involve a young population that often abuses other drugs. Most of these cases do not come to medical attention and often involve other substances added to the mushrooms. Despite the potential for severe toxicity and death, most exposures are relatively benign.\textsuperscript{94,95} Approximately 5\% result in moderate poisoning, with only a few deaths reported per year.

#### Management of Mushroom Exposure

The prognosis depends on the specific species. Identification of the mushroom is the most helpful factor in deciding on a treatment plan. Techniques for mushroom identification are described in most mycology and toxicology textbooks. Local mycologists or a poison center may be helpful. If a specimen is available, it can be stored in a paper bag at room temperature for delivery. Alternatively, a digital picture can be taken and e-mailed.\textsuperscript{4} Vomitus can be collected because mushroom parts

\textbf{BOX 162-1}
may be recovered. Despite these measures, the species is unknown in over 90% of ingestions. Because Amanita species are responsible for most deaths, a clinical strategy for differential diagnosis and management is most often used to identify the highest risk ingestions.

**Mushroom Groups**

Nine general groupings have been found to be useful for clinical management (Table 162-3). These groups can be classified into mushrooms with early onset of symptoms (0–4 hours post ingestion), late onset of symptoms (>6 hours post ingestion), or no symptoms (edible). Mushrooms with serious toxicity and potential for death are in the group that have late onset of symptoms. Particular attention should be paid to the timing of initial symptoms.96–98 Mushroom species often grow together, and foragers frequently pick and eat more than one species of mushroom. The onset of early symptoms does not preclude the diagnosis of a more serious poisoning.

**Early Onset of Symptoms**

Gastrointestinal symptoms of nausea, vomiting, diarrhea, and abdominal cramps are common among many of the mushroom groupings (see Table 162-3). These symptoms are most predominant, however, in the gastrointestinal toxin group. This group contains numerous diverse mushrooms, many with unknown toxins. They cause symptoms rapidly (0.5–3 hours) after ingestion, and symptoms typically last 24 hours. Treatment is supportive, with good outcome expected.

CNS effects are associated with two groups of mushrooms, ibotenic acid/muscimol and psilocybin.95–99 Psilocybin is structurally related to serotonin and lysergic acid diethylamide (LSD). Similar to LSD, hallucinations and CNS effects are prominent. This mushroom is most often used as a drug of abuse.23 Ibotenic acid and muscimol are toxins that are structurally related to glutamic acid and GABA. Glutamic acid is an excitatory neurotransmitter, whereas GABA is an inhibitory one. Lethargy, hallucinations, seizures, or severe agitation begins within 1 to 2 hours after ingestion. Treatment for seizures and supportive care produce a good outcome.

The cholinergic toxidrome is associated with muscarine-containing mushrooms. Muscarine is structurally related to acetylecholine. Because of muscarine’s quaternary structure, it does not cross the blood-brain barrier. Symptoms include salivation, lacrimation, urination, defecation, gastroenteritis, and emesis (SLUDGE). Atropine can be used for severe symptoms. Pralidoxime is not indicated because acetycholinesterase inhibition is not involved.

The final mushroom group that causes early onset of symptoms occurs only with simultaneous ingestion of ethanol. These coprine-containing mushrooms cause a disulfiram-like reaction by blocking acetaldehyde dehydrogenase. The symptoms include flushing, nausea, vomiting, and headache. The onset of this reaction associated with ethanol can occur 30 minutes to several days after mushroom ingestion. Treatment is supportive and similar to disulfiram reactions from other causes.

**Late Onset of Symptoms**

Three groups of mushrooms cause late onset of symptoms (>6 hours post ingestion): cyclopeptide, gyromitrin, and orelline/orellanine. The orelline/orellanine-containing mushrooms are infrequently found in the United States and there have not been any reported cases of toxicity in North America. The cyclopeptide group is responsible for most mushroom-related deaths in the United States.

The cyclopeptide mushrooms contain many species, of which Amanita phalloides is the most well known. Several cyclopeptide toxins have been identified (e.g., amatoxins, virotoxins, phallotoxins) that are thought to be responsible for toxicity.100,101 Initial manifestations, such as severe nausea, vomiting, diarrhea, and abdominal cramping, begin 6 to 24 hours post ingestion. Hydration and supportive care often lead to initial relief of symptoms and a relatively quiescent period. Hepatic toxicity followed by other end-organ involvement may ensue over the next several days to weeks. Progressive elevation of hepatic transaminases, jaundice, and hepatic encephalopathy can lead to death.

Many cases are misdiagnosed as gastroenteritis. Numerous noninvasive therapies have been suggested, including silibinin, thiocic acid, activated charcoal, high-dose penicillin, dexamethasone, vitamin C, cytochrome c, cimetidine, N-acetylcysteine, kutchkin, and asewin.102,103 None of these therapies has been rigorously tested in human-controlled studies. Multidose administration of activated charcoal seems to be effective because of its ability to bind the toxins, availability, and relative safety; however, its effectiveness is unclear.

Numerous invasive therapies also have been proposed for use in cyclopeptide poisoning, including forced diuresis, hemodialysis, hemoperfusion, hemofiltration, plasmapheresis, and hepatic transplantation.104–109 Similar to the noninvasive modalities, it is not clear if any of these therapies are effective. There have been several reports of successful transplantation in severe cases of poisoning105–109; however, it is uncertain what criteria should be used for selecting candidates.110,111 Patients developing severe hepatic signs and symptoms should be considered for transfer to a transplant center.

Gyromitrin-containing mushrooms commonly are mistaken for edible mushrooms as they look similar to Morchella species (morel) mushrooms. The metabolites of this toxin cause GABA
neurotransmitter depletion similar to isoniazid toxicity, leading to excitatory CNS effects, such as headaches, agitation, and seizures. Effects also include nausea, vomiting, and possible hepatotoxicity. The onset of symptoms is at least 6 hours after ingestion. Because of its similarity to isoniazid toxicity, pyridoxine has been proposed as an antidote. It is unclear how effective this antidote is, but it is useful for gyromitrin-induced CNS effects because of its availability and safety profile.

Orelline/orellanine-containing mushrooms have been found in North America. There have been no reports of toxicity associated with cases in the United States, however, with most reported cases in Europe. Symptoms begin 1 to 2 days after ingestion, with nausea, vomiting, abdominal pain, and headache. Renal toxicity manifests days to weeks after these initial symptoms and can progress to chronic renal failure.

Disposition

Initial management is aimed at ruling out mushroom groups associated with early onset of symptoms. If the patient remains asymptomatic after a 3-hour period of observation, the patient should be discharged with instructions to return if any symptoms manifest over the next 72 hours.

**BARBITURATES**

**Perspective**

Barbiturates are discussed in do-it-yourself suicide manuals and have been implicated in the high-profile deaths of Marilyn Monroe, Jimi Hendrix, Abbie Hoffman, Margaux Hemingway, and the mass suicide of 39 members of the Heaven’s Gate cult in 1997. Although barbiturates are still used for seizure disorders, their use as sedatives has declined significantly with the availability of safer alternatives, such as benzodiazepines, resulting in a decline from approximately 1500 barbiturate deaths per year in the 1950s to only six fatalities in 2006.1

Barbiturates are addictive, producing physical dependence and a withdrawal syndrome that can be life-threatening. While tolerance to the mood-altering effects of barbiturates develops rapidly with repeated use, tolerance to the lethal effects develops more slowly, and the risk of severe toxicity increases with continued use.

**Principles of Disease**

Barbiturates depress the activity of all excitable cells, especially those in the central nervous system (CNS) by enhancing the activity of γ-aminobutyric acid (GABA), the major central inhibitor. In acute overdose, barbiturates decrease neural transmission in autonomic ganglia, the myocardium, and the gastrointestinal tract and also inhibit the response to acetylcholine at the neuromuscular junctions.

The GABA_A receptor is a protein complex found on postsynaptic membranes in the CNS. Structurally, it consists of several distinct receptor sites surrounding a chloride ion (Cl^-) channel (Fig. 163-1). GABA opens the chloride channel. The resulting flow of Cl^- into the cell increases the negative resting potential, hyperpolarizing and stabilizing the membrane. There are separate receptor sites for barbiturates and for benzodiazepines and a third site that binds GABA, ethanol, and meprobamate. Although barbiturates and ethanol can directly increase Cl^- conductance, benzodiazepines require the presence of GABA to affect Cl^- flow, which may account for the relative safety of benzodiazepines in comparison with barbiturates.

Barbiturates produce dose-related depressive effects, from mild sedation to coma and fatal respiratory arrest. In the early stages of intoxication, some patients experience euphoria. Barbiturates have no analgesic effect and can paradoxically increase the reaction to pain at low doses.

Barbiturates act directly on the medulla to produce respiratory depression. In therapeutic doses, this respiratory depression mimics that of normal sleep. Starting with doses approximately three times therapeutic, the neurogenic, chemical, and hypoxic respiratory drives are progressively suppressed. Since airway reflexes are not inhibited until general anesthesia is achieved, laryngospasm can occur at low doses.

Therapeutic oral doses of barbiturates produce only mild decreases in pulse and blood pressure, similar to sleep. With toxic doses, more significant hypotension occurs from direct depression of the myocardium along with pooling of blood in a dilated venous system. Peripheral vascular resistance is usually normal or increased, but barbiturates interfere with autonomic reflexes, which then do not adequately compensate for the myocardial depression and decreased venous return. Barbiturates can precipitate severe hypotension in patients whose compensatory reflexes are already maximally stimulated, such as those with heart failure or hypovolemic shock. Barbiturates also decrease cerebral blood flow and intracerebral pressure. Although hypnotic doses of barbiturates do not affect gastric emptying, higher doses can decrease gastrointestinal smooth muscle tone and peristaltic contractions and delay gastric emptying.

Barbiturates are classified according to their onset and duration of action: (1) ultrashort-acting (onset immediate after intravenous dose, duration minutes), (2) short-acting (onset 10–15 minutes after oral dose, duration 6–8 hours), (3) intermediate-acting (onset 45–60 minutes, duration 10–12 hours), and (4) long-acting (onset 1 hour, duration 10–12 hours) (Box 163-1). Only long-acting preparations have anticonvulsant effects in doses that do not cause sedation. Short- and intermediate-acting preparations are almost completely metabolized to inactive metabolites in the liver, while 25% of a phenobarbital (long-acting) dose is excreted unchanged through the kidney. Because phenobarbital is a weak acid (pK_a 7.2), alkalining the urine will increase the amount of drug present in ionized form, minimizing tubular reabsorption and increasing drug clearance. Short- and intermediate-acting barbiturates are not significantly affected by pH changes in this range.

Barbiturates cross the placenta, with fetal levels approaching those of the mother. They are also excreted in low concentration in breast milk. Use during pregnancy is associated with birth defects (category D).
Barbiturates

Clinical Features

Mild barbiturate toxicity mimics ethanol intoxication, presenting with drowsiness, slurred speech, ataxia, unsteady gait, nystagmus, emotional lability, and impaired cognition.

In severe acute intoxication, CNS depression progresses from stupor to deep coma and respiratory arrest. Although pupils are usually normal or small and reactive, concomitant hypoxia can cause pupils to be fixed and dilated. Corneal and gag reflexes may be diminished or absent, muscle tone flaccid, and deep tendon reflexes diminished or absent. Flexor (dorsoflexion) and extensor (decerebrate) posturing can occur in patients comatose from barbiturate intoxication. These neurologic signs are variable and do not always correlate with severity of intoxication or depth of coma. A fluctuating level of consciousness is commonly seen. High barbiturate levels depress gastrointestinal motility, delaying drug absorption. As the drug is metabolized and blood levels drop, peristalsis and drug absorption may increase, causing drug levels to rise.

The life threat of severe barbiturate toxicity is respiratory depression. Because respirations can be rapid but shallow, the degree of hypventilation may not be apparent on clinical examination, but pulse oximetry or capnography will detect the ventilation compromise.

Hypotension is common in patients with severe intoxication, along with a normal or increased heart rate. Barbiturate overdose has been associated with noncardiogenic pulmonary edema. Altered pulmonary capillary permeability can be caused by hypoperfusion, hypoxia, or a direct effect of the drug. Pneumonia may be delayed.

A barbiturate withdrawal syndrome includes tremors, hallucinations, seizures, and delirium (similar to the delirium tremens of ethanol withdrawal). However, severe withdrawal occurs only following dependence on short- or intermediate-acting barbiturates (e.g., pentobarbital, secobarbital, amobarbital, or butalbital). Because these drugs are not commonly used, this syndrome is now rare.

Diagnostic Strategies

The therapeutic level of phenobarbital is 15 to 40 µg/mL (65–172 µmol/L). A serum level greater than 50 µg/mL can be associated with coma, especially in a patient who is not a chronic user. Levels greater than 80 µg/mL are potentially fatal. Serial phenobarbital levels may be helpful in monitoring effectiveness of treatment. Because barbiturates other than phenobarbital have high volumes of distribution, serum levels do not accurately reflect CNS concentrations or correlate with clinical severity. A positive urine screen establishes exposure to a barbiturate but does not prove that the drug is present in toxic amounts and should not be relied upon to explain decreased mental status.

Chest radiographs can detect noncardiogenic pulmonary edema or pneumonia. Computed tomography of the head should be obtained in comatose patients with evidence of trauma, focal neurologic signs, papilledema, or uncertain diagnosis.

Other causes of stupor and coma must be considered and ruled out. Since the electroencephalogram may be silent as a result of barbiturate overdose, no patient should be declared “brain dead” if barbiturates are present at therapeutic levels or greater.

Management

Since barbiturates have no specific antidote, management is based on supportive care, particularly with respect to the cardiovascular and respiratory systems. Severely intoxicated patients are unable to protect their airway adequately and have decreased ventilatory drive. Supplemental oxygen may suffice for patients with mild to moderate overdose, but intubation is often required. Long-term induced paralysis is rarely necessary, and additional sedation usually is unnecessary for mechanical ventilation. Careful fluid replacement should maintain a systolic blood pressure above 90 mm Hg and adequate urine output. Patients must be monitored for fluid overload and pulmonary edema. If vasopressors are necessary, dopamine is preferable to norepinephrine because of its renal vasodilating effects. Active warming should be initiated if the rectal temperature is less than 30°C.

Gastrointestinal Decontamination

Gastric emptying by lavage is not indicated. For large overdoses, there is evidence that clearance of phenobarbital is markedly increased with multidose activated charcoal (MDAC). The dose of activated charcoal is 25 g every 2 hours in an adult; the pediatric dose is 0.5 g/kg every 2 hours. If vomiting occurs, a smaller dose or antiemetics should be used. MDAC can also be administered slowly through a nasogastric tube. Contraindications to MDAC include an unpro-

Disposition
An asymptomatic patient who arrives in the emergency department (ED) after ingesting barbiturates should be observed until 6 hours postingestion and monitored for mental status changes, slurred speech, ataxia, hypotension, and respiratory depression. Onset of symptoms generally occurs within 1 hour of ingestion. Patients who remain asymptomatic and have no significant complicating co-ingestants or medical problems can be discharged or referred for psychiatric care. Patients who are still symptomatic 6 hours after arrival should be admitted for observation.

Benzodiazepines

Perspective
Prior to 1950, drug options for treating anxiety were limited. While meprobamate, first synthesized in 1950, ultimately proved no safer than the barbiturates, its commercial success inspired the development of other nonbarbiturate anxiolytics. With chlordiazepoxide in 1960 and diazepam in 1963, benzodiazepines emerged as the principal agents for the treatment of anxiety. Cardiac effects and fatalities from pure benzodiazepine overdose are rare, and respiratory depression is less pronounced than with barbiturates. Additionally, drug-drug interactions involving benzodiazepines are uncommon.

Benzodiazepines remain among the most widely prescribed class of drugs (Table 163-1). With nearly 50 individual agents available worldwide, they account for two thirds of all psychotropic drug prescriptions. Benzodiazepines are the most common prescription drugs for attempting drug-assisted suicide. Despite such frequent misuse, the vast majority of benzodiazepine overdoses follow a relatively benign clinical course. Children make up 10% of benzodiazepine overdose cases.

Principles of Disease
Benzodiazepines produce sedative, hypnotic, anxiolytic, and anticonvulsant effects by enhancing the inhibitory actions of GABA. Binding of a benzodiazepine to a specific benzodiazepine receptor potentiates GABA effects on the chloride channel at the GABA<sub>A</sub> receptor, increasing intracellular flux of chloride ions and hyperpolarizing the cell. The net effect is a diminished ability of the nerve cell to initiate an action potential, resulting in inhibition of neural transmission.

Three unique benzodiazepine receptors have been identified. The distribution of these receptors varies throughout the central and peripheral nervous systems. Classic benzodiazepines are nonselective, producing a broad range of clinical effects. Newer benzodiazepines interact selectively with a single receptor subtype to achieve a desired result, such as sedation, while minimizing unnecessary effects.

Pharmacokinetics
Benzodiazepines are rapidly absorbed orally. Intramuscular use of chlordiazepoxide and diazepam is limited by erratic absorption, but both lorazepam and midazolam are predictably absorbed after intramuscular injection. Following absorption, benzodiazepines distribute readily and penetration of the blood-brain barrier is facilitated by their highly

</table>
lipophilic structure. In plasma, benzodiazepines are highly protein-bound.7

Metabolism of all benzodiazepines occurs in the liver. Oxazepam, temazepam, and lorazepam are directly conjugated to an inactive, water-soluble glucuronide metabolite that is excreted by the kidney. Other benzodiazepines must first be converted by the hepatic cytochrome P-450 system. Chlordiazepoxide, diazepam, flurazepam, and clorazepate are metabolized to active derivatives that are then slowly conjugated and excreted. The long elimination half-lives of these intermediates can cause accumulation in the body with repeated dosing. Triazolam, alprazolam, and midazolam are converted to hydroxylated intermediates that, although active, are very rapidly conjugated and excreted and do not contribute significantly to the drug’s overall pharmacologic effect.7

Cytochrome P-450 processes may be significantly impaired in elderly patients or those with liver disease, leading to prolonged elimination of some benzodiazepines. Co-ingestion of drugs that also undergo cytochrome P-450 metabolism (e.g., cimetidine, ethanol) prolongs the halflives of these benzodiazepines, but the clinical significance of these interactions is unclear.8

Clinical Features

Central nervous system depression is common in patients with benzodiazepine poisoning and ranges from mild drowsiness to coma. Significant respiratory depression is rare, but can be seen with large oral overdoses or during intravenous conscious sedation, particularly when the benzodiazepine is combined with an opioid such as fentanyl.9 Hypotension is uncommon. Other complications include aspiration pneumonia and pressure necrosis of skin and muscles.

The vast majority of children develop symptoms within 4 hours of benzodiazepine ingestion. Ataxia is the most common sign of toxicity, occurring in 90% of patients. In children, respiratory depression occurs in less than 10% of cases and hypotension has not been reported.

Diagnostic Strategies

Any patient with altered mental status should have a blood glucose level rapidly determined. Qualitative immunoassays for benzodiazepines in urine are available but do not aid management decisions. Many of these tests detect only benzodiazepines that are metabolized to oxazepam glucuronide; therefore, clonazepam, lorazepam, midazolam, and alprazolam are not detected on a urine drug screen.10 Serum drug concentrations are not routinely available and do not correlate with clinical severity.

The benzodiazepine antagonist flumazenil should not be routinely administered to patients with coma of unknown origin or suspected benzodiazepine overdose.11 Any possibility of concomitant tricyclic overdose contraindicates flumazenil use.9

Differential Considerations

Benzodiazepine overdose is usually suspected or diagnosed because of the clinical presentation. Many patients are arousable and can provide supporting information. Atypical or focal findings can be clues to the presence of other conditions. Profound coma or cardiopulmonary instability with pure benzodiazepine overdose is rare, and the presence of either should prompt the search for a co-ingestant. Nontoxicologic causes of CNS depression should also be considered.

Management

General

Initial stabilization, including endotracheal intubation, must not be delayed by administering antidote. The vast majority of benzodiazepine overdoses can be managed expectantly. Activated charcoal is generally not beneficial in overdose.12 MDAC, hemodialysis, and whole bowel irrigation are not indicated or effective in benzodiazepine overdose.

Antidote

Flumazenil, a nonspecific competitive antagonist of the benzodiazepine receptor, can reverse benzodiazepine-induced sedation after general anesthesia, procedural sedation, and overdose, but is not recommended for the reversal of benzodiazepine overdose in the ED. Although theoretical benefits of flumazenil use include cost savings and avoidance of procedures and tests such as endotracheal intubation and lumbar puncture, several studies have not been able to demonstrate an actual benefit.13 Seizures and cardiac dysrhythmias can occur with flumazenil administration, and fatalities have been reported.14-16 Flumazenil is especially hazardous when given to patients who are habituated to benzodiazepines, in whom acute benzodiazepine withdrawal, including refractory seizures, can be induced, and also when seizure-causing drugs (such as cocaine or a tricyclic antidepressant) have also been ingested, due to loss of the benzodiazepine’s protective anti-convulsant properties. Co-ingestants that cause dysrhythmias, such as carbamazepine or chloral hydrate, may increase the likelihood of cardiac effects.9 Other risk factors are summarized in Box 163-2. One study found that 12% of patients receiving flumazenil after known pure or mixed benzodiazepine overdose actually had a contraindication to its use.17

</table>
The initial adult dose of flumazenil is 0.2 mg given intravenously over 30 seconds. A second dose of 0.3 mg may be given, followed by 0.5-mg doses at 1-minute intervals, to a total of 3 mg. Most patients respond within 3 mg. In children, the initial dose is 0.01 mg/kg (up to 0.2 mg). Because the duration of action of flumazenil is short (0.7–1.3 hours), resedation occurs in up to 65% of patients and requires either redosing or continuous infusion (0.25–1.0 mg/hr).

In summary, benzodiazepine overdose requires only supportive care (including, in some cases, intubation). Flumazenil may precipitate seizures or acute withdrawal. It should be used only in highly selected cases, such as small children with accidental poisoning or for reversal of accidental overdose of benzodiazepines during procedural sedation. When flumazenil is used, careful monitoring is necessary because of the risk for persistent respiratory depression or resedation. Use of flumazenil has not consistently altered outcome, complication rate, number of costly procedures performed, or duration of hospital stay in ED patients.17

**Disposition**

Patients remaining asymptomatic after 4 to 6 hours of ED observation may be medically cleared. For cases of deliberate overdose, appropriate psychiatric consultation should be obtained.

**Benzodiazepine Withdrawal Syndrome**

Abrupt discontinuation of a benzodiazepine in a chronic user results in a characteristic constellation of symptoms (Box 163–3). Risk for withdrawal is a function of both the dose of benzodiazepine and the duration of its use. Continuous treatment for more than 4 months is generally required before a patient is at risk for withdrawal. With abrupt discontinuation of a benzodiazepine, the most severe withdrawal symptoms are expected within several days to a week.18 Use of flumazenil can precipitate immediate withdrawal symptoms. Treatment of withdrawal consists of restarting benzodiazepines.

**FLUNITRAZEPAM**

Flunitrazepam (Rohypnol) has been used in Europe, Asia, and Latin America for insomnia and preoperative sedation since 1975. Although never manufactured or sold in the United States, flunitrazepam has been implicated in many reports of “date rape” incidents. Flunitrazepam has been an active agent in the illicit drug market, where it is used to alter the effects of other drugs, including heroin and cocaine.19 Flunitrazepam has 10 times more affinity than diazepam for certain benzodiazepine receptors. Onset of CNS depression occurs within 30 minutes. The drug is most frequently ingested with alcohol, producing disinhibition and amnesia. Despite marked CNS depression, patients can usually be aroused with noxious stimuli. The half-life of the drug is 16 to 35 hours, but coma can be prolonged for up to 48 hours.19 Flunitrazepam is easily obtainable outside the United States. The drug is not detected on routine urine drug screens but, if needed as evidence, urine should be collected and refrigerated or frozen and the local or state police crime laboratory contacted to arrange specific testing. Metabolites of flunitrazepam are detectable in the urine up to 72 hours after exposure.20

**BUSPIRONE**

Buspirone (BuSpar) has been used for generalized anxiety since 1986. Unlike benzodiazepines, buspirone does not have any effect on GABA. Rather, it acts as a partial serotonin (5-HT1A) agonist. To a lesser extent, it also antagonizes dopamine (D2) receptors. Buspirone has no hypnotic, anticonvulsant, or muscle relaxant effects.

Buspirone has several advantages over benzodiazepines. The drug causes minimal CNS depression, even in combination with ethanol. Dosage adjustment is not needed for elderly patients. Chronic administration does not cause tolerance, and dependence does not occur. A withdrawal state after discontinuation has not been reported.

Only one case of isolated buspirone overdose has been published. That patient was lethargic and had a tonic-clonic seizure but recovered fully.21

**ZOLPIDEM AND ZALEPLON**

Zolpidem (Ambien) and zaleplon (Sonata) differ in structure from both the benzodiazepines and buspirone, and neither is detected on a benzodiazepine toxicology screen. They act selectively at a specific benzodiazepine receptor, producing sedation without many of the side effects seen with benzodiazepines. They have modest anxiolytic, muscle relaxant, and anticonvulsant properties. Significant drug interactions are rare. Compared with zolpidem, zaleplon causes less memory loss and sedation at therapeutic doses and is more rapidly eliminated.22 Transient visual disturbances and hallucinations can occur in patients with normal levels of consciousness with both zolpidem and zaleplon.22,23 Abuse of zolpidem is limited by vomiting, which may occur after a supratherapeutic dose. Both zolpidem and zaleplon are rapidly eliminated and lack active metabolites.24

Patients with zolpidem overdose do well with supportive care alone. Fatalities from isolated zolpidem overdose are rare. All published cases involve individuals found dead at home and are often associated with co-ingestants, particularly other sedative hypnotics or antipsychotics.25 Drowsiness is by far the most common symptom. Coma and respiratory failure are rare, despite overdoses of up to 40 times the normal dose, although intubation may be required, particularly if there are co-ingestants.26 Zolpidem overdose in children follows a similarly benign course. Drowsiness, ataxia, and hallucinations resolve within 10 hours.27

Overdose information for zaleplon is limited. In one case series, patients had CNS depression and mild hypotension. Arousal was temporally associated with flumazenil use in one patient.28 The only published fatality involves a mixed drug overdose with unknown quantities of zaleplon and butalbital, with postmortem serum zaleplon concentration 40 times greater than therapeutic.29 Adverse effects with therapeutic use include headache, anterograde amnesia, and transient visual hallucinations.24

**ESZOPICLONE**

Eszopiclone (Lunesta) has been marketed in the United States since 2005 for treating insomnia. It is the S-isomer of racemic zopiclone, which has been used for decades outside the United States, for insomnia and preoperative sedation since 1986. Unlike benzodiazepines, buspirone does not have any effect on GABA. Rather, it acts as a partial serotonin (5-HT1A) agonist. To a lesser extent, it also antagonizes dopamine (D2) receptors. Buspirone has no hypnotic, anticonvulsant, or muscle relaxant effects.

Buspirone has several advantages over benzodiazepines. The drug causes minimal CNS depression, even in combination with ethanol. Dosage adjustment is not needed for elderly patients. Chronic administration does not cause tolerance, and dependence does not occur. A withdrawal state after discontinuation has not been reported.

Only one case of isolated buspirone overdose has been published. That patient was lethargic and had a tonic-clonic seizure but recovered fully.21

**ZOLPIDEM AND ZALEPLON**

Zolpidem (Ambien) and zaleplon (Sonata) differ in structure from both the benzodiazepines and buspirone, and neither is detected on a benzodiazepine toxicology screen. They act selectively at a specific benzodiazepine receptor, producing sedation without many of the side effects seen with benzodiazepines. They have modest anxiolytic, muscle relaxant, and anticonvulsant properties. Significant drug interactions are rare. Compared with zolpidem, zaleplon causes less memory loss and sedation at therapeutic doses and is more rapidly eliminated.22 Transient visual disturbances and hallucinations can occur in patients with normal levels of consciousness with both zolpidem and zaleplon.22,23 Abuse of zolpidem is limited by vomiting, which may occur after a supratherapeutic dose. Both zolpidem and zaleplon are rapidly eliminated and lack active metabolites.24

Patients with zolpidem overdose do well with supportive care alone. Fatalities from isolated zolpidem overdose are rare. All published cases involve individuals found dead at home and are often associated with co-ingestants, particularly other sedative hypnotics or antipsychotics.25 Drowsiness is by far the most common symptom. Coma and respiratory failure are rare, despite overdoses of up to 40 times the normal dose, although intubation may be required, particularly if there are co-ingestants.26 Zolpidem overdose in children follows a similarly benign course. Drowsiness, ataxia, and hallucinations resolve within 10 hours.27

Overdose information for zaleplon is limited. In one case series, patients had CNS depression and mild hypotension. Arousal was temporally associated with flumazenil use in one patient.28 The only published fatality involves a mixed drug overdose with unknown quantities of zaleplon and butalbital, with postmortem serum zaleplon concentration 40 times greater than therapeutic.29 Adverse effects with therapeutic use include headache, anterograde amnesia, and transient visual hallucinations.24

**ESZOPICLONE**

Eszopiclone (Lunesta) has been marketed in the United States since 2005 for treating insomnia. It is the S-isomer of racemic zopiclone, which has been used for decades outside the United States.
States. Eszopiclone has a structure unrelated to those of benzodiazepines, barbiturates, zolpidem, and zaleplon.

The mechanism of eszopiclone’s action is not completely described but may involve a specific GABA<sub>A</sub> receptor close to or coupled with the benzodiazepine receptor. Eszopiclone is rapidly absorbed, with a peak serum level at 1 hour and a half-life of 6 hours. It is metabolized in the liver to minimally active metabolites. The usual bedtime dose is 3 mg. It is recommended that elderly patients and those with hepatic insufficiency be treated with a lower (1 mg) dose.

Adverse effects seen with therapeutic use of eszopiclone include drowsiness, dizziness, dry mouth, unpleasant taste, nausea, and vomiting. Auditory and visual hallucinations have been reported. Experience with eszopiclone overdose is limited, but treatment is supportive. A retrospective case review described 525 eszopiclone ingestions, but 259 of these patients had also ingested other drugs or chemicals. The ingestions involved eszopiclone doses up to 210 mg and presented with mild to moderate symptoms at most. Two deaths occurred, both involving significant co-ingestants. A single case report described a 52-year-old man who developed coronary vasospasm and a ventricular fibrillation arrest after ingesting 45 to 60 mg of eszopiclone. However, the arrest occurred approximately 20 hours after ingestion, and it is unclear what role, if any, eszopiclone played in causing the arrest.

**CHLORAL HYDRATE**

**Perspective**

Deaths related to chloral hydrate overdose were first reported in the medical literature in 1890. Chloral hydrate has a low therapeutic ratio and can produce significant, potentially fatal, toxicity. While chloral hydrate use is rare today, it is still occasionally prescribed as a sedative in the elderly and for sedation in children undergoing medical procedures. The hypnotic oral adult dose is 0.5 to 1.0 g. The toxic oral dose in adults is approximately 10 g and may be as little as 1.5 g in a child.

The toxic effects of chloral hydrate include CNS depression, gastrointestinal irritation, cardiovascular instability, hepatitis, and proteinuria. The primary active metabolite of chloral hydrate, trichloroethanol, has a barbiturate-like effect on GABA<sub>A</sub> receptors and is responsible for most of the CNS depression seen with significant overdose.

Chloral hydrate is rapidly absorbed from the gastrointestinal tract and almost immediately metabolized to trichloroethanol by the enzyme alcohol dehydrogenase. Onset of action is 20 to 30 minutes. Trichloroethanol is long-acting, with a half-life that can be significantly prolonged after overdose as metabolic pathways become saturated.

The combination of chloral hydrate and ethanol (the “Mickey Finn”) potentiate each other’s action to produce rapid loss of consciousness. Chloral hydrate increases the half-life of ethanol by competitively inhibiting the enzyme alcohol dehydrogenase, and the metabolism of ethanol generates NADH, a cofactor for the conversion of chloral hydrate to trichloroethanol.

**Clinical Features**

Chloral hydrate toxicity causes CNS and respiratory depression, gastrointestinal irritation, cardiovascular instability, and dysrhythmias. The combination of deep coma and cardiac dysrhythmia without hypoxia is characteristic of severe cases.

Mild chloral hydrate toxicity can mimic ethanol or barbiturates, with drowsiness, ataxia, and lethargy. A pear-like odor to the patient’s breath or gastric contents may suggest the diagnosis. More severe toxicity includes miosis, muscle flaccidity, diminished deep tendon reflexes, hypoventilation, hypotension, and hypothermia.

Chloral hydrate is corrosive and causes nausea, vomiting, esophagitis, hemorrhagic gastritis and, more rarely, gastrointestinal perforation or necrosis.

Transient hepatic or renal dysfunction can also occur.

Dysrhythmias from chloral hydrate toxicity can be fatal. Chloral hydrate decreases myocardial contractility, shortens the cardiac refractory period, and increases the sensitivity of myocardium to catecholamines. Dysrhythmias include atrial fibrillation, supraventricular tachycardia, ventricular tachycardia, multifocal premature ventricular contractions, torsades de pointes, ventricular fibrillation, and asystole. Hypotension results from inhibition of central neurovascular regulatory centers as well as impaired myocardial contractility.

**MANAGEMENT FOR SEDATIVES**

The key to management for all of these agents is support of cardiorespiratory function. Intubation may be required for airway protection or to support ventilation and oxygenation. Avoid naloxone or flumazenil, which may precipitate ventricular dysrhythmias. Because chloral hydrate sensitizes myocardium to catecholamines, epinephrine and norepinephrine should also be avoided. Standard antidysrhythmic agents such as lidocaine do not appear effective against chloral hydrate–induced cardiac ectopy. The treatment of choice is a beta-blocker. Intravenous propranolol can be given in adult doses of 0.5 mg until ectopy is suppressed, followed by an infusion of 1 to 2 mg/hr, titrated to a heart rate of 80 to 100 beats per minute. A short-acting agent such as esmolol can also be used. Torsades de pointes should be treated with intravenous magnesium or overdrive pacing. Type I antidysrhythmic agents such as quinidine should be avoided. Unstable patients not responding to conservative therapy can be treated with hemoperfusion or hemodialysis.

**OVER-THE-COUNTER SLEEP AIDS**

**Perspective**

In the past, most over-the-counter (OTC) sleep aids contained a combination of an antihistamine (either diphenhydramine or pyrilamine) and scopolamine. Some preparations also contained a bromide. For safety reasons, these products were reformulated in the late 1980s to contain diphenhydramine or doxylamine, now the only two drugs found in nonprescription hypnotics. Many preparations also contain acetaminophen or aspirin, added to create a nighttime pain reliever (Table 163-2). The availability and frequent use of these agents may explain why overdose is so common.

**Principles of Disease**

Diphenhydramine and doxylamine are antihistamines that also have hypnotic, anticholinergic, and weak local anesthetic properties. They act as competitive antagonists of H<sub>1</sub> histamine receptors and cause sedation by inhibiting the actions of acetylcholine on muscarinic receptors in the CNS.

The pharmacokinetic profiles of diphenhydramine and doxylamine are similar. Both are rapidly absorbed, with peak plasma levels occurring at 1 to 2 hours after administration. In the systemic circulation, they are highly protein-bound, with large volumes of distribution. Extensive metabolism occurs in the liver by the cytochrome P-450 system. The elimination half-life is 4 hours for diphenhydramine and 9 hours for doxylamine.
Clinical Features

Impaired consciousness is the most frequent finding with diphenhydramine overdose. Somnolence, psychotic behavior, and agitation are common. Anticholinergic effects may be apparent, as noted in Chapter 148. Apart from a lower incidence of psychosis, doxylamine has toxicity similar to that of diphenhydramine. Seizures and rhabdomyolysis may occur with severe toxicity. Serious cardiotoxicity is rare.

Diagnostic Strategies

Some comprehensive urine drug immunoassays will detect diphenhydramine. Quantitative serum levels of diphenhydramine or doxylamine are neither routinely available nor clinically useful. Serum acetaminophen and salicylate concentrations should be measured in patients with OTC sleep aid overdoses, because many preparations contain both a hypnotic and an analgesic. Measuring serum creatine phosphokinase and urinary myoglobin may help detect myoglobinuria.

Management

Management of mild to moderate toxicity from OTC sleep aid overdose is generally supportive. Specific details regarding anticholinergic toxicity are discussed in Chapter 148.

Disposition

Patients with minor sedation or anticholinergic effects that are resolving or who remain asymptomatic or are minimally symptomatic after a 4-hour observation period can be medically cleared. If the ingestion was in the context of self-harm, psychiatric evaluation is indicated. Other patients require inpatient observation in a monitored setting.
GHB is lipophilic and rapidly absorbed. Onset of symptoms occurs within 15 to 30 minutes and peak plasma levels within 20 to 60 minutes. Unlike GABA, it readily crosses the blood-brain barrier. The half-life of GHB is 27 minutes but may increase at high doses.

GBL is an industrial solvent that is rapidly absorbed after ingestion and metabolized within minutes to GHB by peripheral and hepatic lactonases. Before conversion to GHB, GBL itself is inactive and has no sedating effects. It produces a clinical syndrome similar to that of GHB ingestion, but its effects are greater and more prolonged. In fact, GBL is more efficient at delivering GHB to the CNS than GHB itself. GBL is available under a number of street names (Box 163-5).

1,4-Butanediol (1,4-BD) is converted after ingestion to GHB by the enzyme alcohol dehydrogenase. Like GBL, it is used as an industrial solvent. Unlike GBL, 1,4-BD itself has sedative-hypnotic effects. Clinical findings are similar to GHB. When 1,4-BD and ethanol are ingested together, ethanol acts as a competitive inhibitor of alcohol dehydrogenase, so the toxic effects of 1,4-BD are delayed and prolonged, and the risk of death is increased. 1,4-BD is available under a number of street names (Box 163-6).

In 2007, a children’s toy marketed under the names Aqua Dots and Bindez Beads was contaminated when 1,4-BD was substituted for a more expensive industrial solvent during the manufacturing process. The toy consisted of tiny brightly colored spheres that were readily ingested by toddlers, causing decreased levels of consciousness, coma, or apparent seizures.

### Clinical Features

Diagnosis of GHB intoxication is based on the history and clinical course. Rapid recovery from coma, or periods of agitation alternating with periods of decreased level of consciousness, is characteristic. Signs and symptoms are generally consistent with poisoning by other sedative-hypnotic agents. Hypothermia may occur. In the presence of coma, bradycardia with or without hypotension may be seen and occasionally responds to stimulation alone. Eye examination may reveal miosis with or without nystagmus. Behavioral changes are most common and range from aggression and delirium to coma. A distinctive feature of GHB intoxication is respiratory depression with apnea, interrupted by periods of agitation and combativeness, especially stimulated by attempts at intubation that do not use RSI drugs. Emesis occurs in 50% of cases. Generalized seizures may actually represent random myoclonic movements of the face and extremities. The dose-response curve of GHB is steep. An oral dose of 10 mg/kg results in hypotonia and amnesia, whereas 25 mg/kg induces sleep. A dose of 50 to 60 mg/kg produces anesthesia, and higher doses may cause coma associated with bradycardia, respiratory depression, vomiting, and myoclonic activity. The severity is also dependent on the dose and the concurrent use of alcohol or other psychoactive drugs.

### Diagnostic Strategies

GHB is not detected on most urine toxicology screens. If laboratory confirmation is required, specimens must be collected early to capture the parent compound, and gas chromatography-mass spectroscopy must be performed. The drug may be detected in urine up to 12 hours after ingestion. Poisoning with another sedative hypnotic can produce a similar clinical picture to that seen with GHB. Unique to GHB, however, is the relatively rapid resolution of symptoms. In the absence of a co-ingestant such as ethanol, most patients will awaken within 3 to 4 hours. Nearly all patients recover fully within 8 hours. Prolonged coma should prompt a search for another cause. Cardiac effects and refractory seizures are rare and suggest the presence of other agents.

### Management

Because of the high incidence of emesis with GHB overdose, intubation for airway protection should be seriously considered in patients with significant CNS depression. In the absence of an identified difficult airway, rapid sequence intubation is the method of choice. Bradycardia unresponsive to stimulation can be treated with atropine. Treatment of isolated GHB ingestion is supportive. Patients should be protected from self-injury until resolution of symptoms. Physostigmine had been used as an antidote for GHB when used as an anesthetic agent, but the use of physostigmine is not generally recommended.

### Withdrawal

Similar to other sedatives and hypnotics, patients who suddenly stop GHB or its precursors after chronic, frequent use can experience a severe and potentially life-threatening withdrawal syndrome. Because of the short half-life of GHB, symptoms of withdrawal usually begin within several hours of...
the last dose. The typical patient will have been using these products for weeks or years, every 1 to 3 hours around the clock to avoid withdrawal symptoms.

Mild withdrawal presents with anxiety, tremor, and insomnia. This can progress to confusion, delirium, overt psychosis, paranoid ideation, hallucinations (visual, aural, and/or tactile), and autonomic instability. Diagnosis relies on a history of symptoms beginning after abruptly ceasing use of these products. The differential diagnosis includes withdrawal from other sedatives or hypnotics, delirium tremens, sympathomimetic toxicity, serotonin syndrome, neuroleptic malignant syndrome, CNS infection, and thyroid storm.

Initial treatment usually begins with high-dose benzodiazepines. However, GHB withdrawal may involve depleted levels of GABA. Since the effect of benzodiazepines requires the presence of GABA, they may not be effective in controlling GHB withdrawal. Barbiturates, such as pentobarbital, which do not need GABA to be effective, are often required in cases of severe intoxication.

These patients often require intensive care admission for high-dose sedatives to manage agitation and to monitor fluctuating vital signs. Rhabdomyolysis and severe hyperthermia should be ruled out. Deaths have been reported, sometimes many days after presentation and after apparent improvement.

Disposition

Because of GHB’s short half-life, symptoms often resolve while the patient is still in the ED. The patient generally regains consciousness spontaneously. No delayed toxicity is expected. Patients should be counseled about the seriousness of GHB intoxication.
Special Populations
PERSPECTIVE

Background
Assessment of pediatric patients from the newly born through adolescence offers unique and varied challenges to the emergency care provider. Approximately 30% of all visits to a general emergency department (ED) are for issues related to pediatric patients. The vast majority of children in crisis are not seen in pediatric specialty hospitals, but in community hospital EDs. Although most pediatric visits to the ED are not serious, it is not uncommon to see true emergencies in infants and young children. Serious and life-threatening pediatric emergencies result from a wide variety of causes and require the health care provider to understand the unique anatomic, physiologic, immunologic, and developmental differences that make serious problems often difficult to recognize and the differential diagnosis dependent on the age of the patient.

Emergency care does not stop or start in the ED. An integrated emergency medical system that is capable of responding to the needs of children is a critical part of pediatric emergency care. Likewise, many critically ill or injured children cannot receive definitive care in small community hospitals. Therefore, a support network that includes interfacility transport resources and definitive care for pediatric patients must be part of an integrated system of emergency care for children. This chapter focuses on the role of the emergency physician in recognizing and assessing children needing emergency care.

Epidemiology
According to the National Center for Health Statistics, there were approximately 115,300,000 ED visits in the year 2003. In 2005, 20.5% of ED visits were for patients less than 18 years of age, and 28.2% of all children under 6 years of age in the United States had at least one visit to an ED in the past 12 months. The National Hospital Ambulatory Medical Care Survey in 2005 demonstrated that the age group with the highest annual per capita ED visit rate was infants under 12 months of age, with 91.3 visits per 100 infants. A recent survey revealed that pediatric patients were seen in an adult facility 89% of the time, with only 4% of departments having a separate area designated for the care of children. The Emergency Pediatric Services and Equipment Supplement to the National Hospital Ambulatory Medical Care Survey revealed that 23% of EDs have a Pediatric Emergency Medicine specialist available, 62% have pediatric attending physicians available, and 71% have emergency medicine physicians on staff. Only 6% of EDs have all the supplies as recommended by the joint American Academy of Pediatrics/American College of Emergency Physicians policy, “Care of Children in the Emergency Department: Guidelines for Preparedness.” Fifty percent of departments have at least 85% of the recommended supplies.

Data continue to suggest that health insurance status is not a significant cause of ED overcrowding. Access to pediatric care is associated with a marked decrease in ED utilization regardless of insurance status, especially among the uninsured. The convenience of the ED, access without appointment, and lack of understanding by parents of the meaning of an emergency are the major factors related to pediatric nonurgent visits.

Respiratory emergencies and trauma are the most common reasons for visits to an ED. Table 164-1 provides a list of the most common problems presenting to a pediatric ED. The most common diagnoses include acute respiratory infection, fever, otitis media and other head and neck infections, enteritis, and minor cuts and contusions. Injury is the most common cause of serious morbidity and mortality in children younger than 15 years and is responsible for 14.1 ED visits per 100 persons per year. In the pediatric age group, approximately 95% of these visits are for unintentional injuries that are largely predictable and preventable. Although the reasons for pediatric ED visits are many and varied, the care of critically ill or injured children should always focus on two physiologic events: shock and respiratory failure.

PRINCIPLES OF DISEASE

Pathophysiology

Anatomic and Physiologic Differences
Physical assessment of a pediatric patient requires attention to a variety of anatomic, physiologic, and developmental differences that vary with the age of the patient. It is sometimes difficult to separate anatomic and physiologic issues; for example, the large surface area-to-weight ratio in young infants can result in heat loss and temperature instability. Thus, it is important to maintain a neutral thermal environment during the physical assessment and stabilization process.

The relatively large head-to-body ratio and the small, weak neck of infants and young children make them particularly prone to head injuries. Blunt trauma to the chest and abdomen often results in injury to internal organs with minimal or no
external signs of trauma. The elasticity of growing bones creates unique problems in pediatrics. Soft and pliable growing ribs will bend rather than break and transmit the forces of blunt trauma to the thoracic and upper abdominal organs. The weakest part of growing bones is the ph ysical plate or growth plate, and this area is injured more frequently than the surrounding ligaments. In a growing child, sprains are uncommon and physeal fractures result in nearly 20% of pediatric fractures. Recognition of growth plate injuries in children is critical to avoid imbalance in bone growth.

Anatomic differences between the pediatric and adult airway are important to understand for appropriate assessment and emergency support of the airway when required. The small airways of infants and young children are more prone to obstruction from secretions, which can result in relatively rapid deterioration ranging from respiratory distress to failure. Simple maneuvers such as deep suction of the upper airway at the larynx and obtaining a blood pressure measurement in patients of all ages should be attempted.

Table 164-2 provides normal ranges of vital signs. It is imperative for the provider to be familiar with these different values as they vary with age. Recognition and explanation for abnormal vital signs is one of the keys to success in the treatment of the ill patient.

Normal heart rate varies with age. Tachycardia can be a product of fever, anxiety, pain, or fear but is also the first and most sensitive sign of cardiovascular compromise in the pediatric patient. When measuring the heart rate, the quality of the pulse can be extremely helpful, as can a comparison of the strength of the central and peripheral pulses in the same extremity. The quality of the brachial and radial pulses or the femoral and dorsalis pedis pulses palpated concurrently provides important information to differentiate cardiovascular compromise from benign causes of tachycardia. Bradycardia can be an ominous sign in the ill patient heralding cardiopulmonary failure and impending cardiac arrest.

Blood pressure measurement is a key component of the assessment of cardiovascular function and should be obtained in ill patients of all ages. Infants and young children have excellent compensatory measures for maintaining blood pressure in the presence of significant loss of circulatory volume. Compensatory mechanisms include an increase in heart rate and systemic vascular resistance. When these compensatory mechanisms fail and blood pressure drops below normal, the patient moves from a state of compensated to decompensated shock. Obtaining an accurate blood pressure in infants and small children can be challenging. The most common hurdle is the lack of cooperation by infants and small children. Another hurdle is the appropriate selection of the blood pressure cuff. The properly sized cuff should cover approximately two thirds of the circumference of the upper arm and extend at least 50% of the length of the upper arm.

The lower limit for acceptable blood pressure in children older than 1 year can be quickly estimated by using the following formula: systolic blood pressure (mm Hg) = 70 + (2 × age in years). The pulse oximetry waveform can also be used to determine systolic blood pressure. Observing for the return of a plethysmographic waveform of the pulse oximeter as the blood pressure cuff is deflated has been shown to correlate closely with conventional methods of blood pressure measurement. Whenever possible, blood pressure should be obtained in all patients. An alert and crying infant with good peripheral pulses and normal mental status can be assumed to have adequate blood pressure, but this assumption can be misleading, and obtaining a blood pressure measurement in patients of all ages should be attempted.

As with the heart rate, respiratory rate varies with the age of the patient. Respiratory rate alone cannot be used to deter-
mine adequacy of ventilation. The respiratory rate must be compared with the adequacy of air exchange and work of breathing when assessing ventilation. Tachypnea can be the first and most sensitive sign of respiratory compromise in the pediatric patient. Tachypnea, however, is nonspecific and can also be a product of fever, fear, anxiety, or pain. In a febrile infant, the respiratory rate will increase by up to five respirations per minute for every degree centigrade in temperature elevation. Either a slow or rapid respiratory rate can be a sign of impending respiratory failure. Periodic breathing is a common reason for an ED visit by concerned, often first-time parents. It is not at all unusual for infants to have periodic breathing with episodes of apnea lasting up to 20 seconds. To be considered abnormal, periodic breathing must be associated with a drop in heart rate or oxygen saturation.

Vital signs at one given point in time may be quite difficult to interpret. Repeated measurement of the respiratory rate, heart rate, and blood pressure over time will provide a more accurate assessment of a patient’s physiologic condition. Again, it is imperative that the provider find an explanation for any abnormal vital sign before disposition of the patient.

Developmental Issues

Knowledge of basic behavioral and developmental differences by age is important when assessing a pediatric patient. Table 164-3 summarizes age-related pediatric differences in motor function, problem-solving, language, and social/adaptive milestones during the first 2 years.

Neonates

During the neonatal period and early infancy, normal behavior consists of sleeping, feeding, and crying when hungry or experiencing discomfort. There is little or no eye contact and no social smile. Discomfort is usually nonspecific, and the cause of the irritability or crying may be difficult to interpret. It is essential in the assessment of the infant for the provider to listen to the parents and their concerns. A mother’s “sense” of her child is often accurate and should be considered seriously.

Infants (12 Months or Younger)

By 2 to 3 months an infant has a social smile and responds to a friendly voice. Lack of appropriate social interaction can be worrisome. An infant with a glassy-eyed, “nobody home” stare can be easily distinguished from a normal infant who tracks lights or has a smiling face. Infants at this age have little or no understanding of language, but they will certainly respond to a calm and soothing voice. Of concern is a 6-month-old who does not acknowledge your presence. Normal behavior for this age includes any expression of curiosity or anxiety, such as crying. Children older than 6 months should be approached with caution. Infants at this age will cry when taken from the safety of their caregiver’s arms. The emergency physician should anticipate stranger anxiety and examine the patient, whenever possible, in the lap of the caregiver. Distractions such as toys and penlights are useful to provide emotional control of the infant during the examination.

Toddlers (13 Months to 3 Years of Age)

During the toddler age, as language develops, it is important to talk directly to the child. It is important to realize that toddlers and preschoolers have more extensive receptive language than expressive language and can pick up fears and concerns from their parents and caregivers, making them apprehensive and fearful. If the patient appears stable, sitting and talking or playing with the patient first rather than performing the examination immediately upon entering the examination room can help establish a rapport. Praise and reassurance during the examination can go a long way in maintaining this rapport with the child.

Preschool Children (4 to 5 Years of Age)

Preschool children often fantasize, and such fantasies may result in irrational assumptions and even nightmares. The child may sense the fears and concerns of their caregivers and this may contribute to these assumptions. The cause of injuries or illnesses in preschoolers or loved ones may be misinterpreted as being a result of their own misbehavior. The provider can expedite the examination in a toddler by allowing the child to control some part of his or her experience, such as picking which ear the provider examines first.

School-Age Children (6 to 12 Years of Age)

As children reach school age, it becomes particularly important to explain procedures, answer questions, and address fears and concerns honestly. Privacy and modesty should be respected. Whenever possible, the child should be included in conversations, and historical information should be taken from both the child and parent. The powers of reasoning begin to mature, and a school-age child will often attempt to negotiate control over having painful or distasteful procedures performed. Choices and behavior limits should be given only when they do not compromise care. A child may be given some autonomy by allowing them to make choices in their care such as the choice to have blood drawn from the left arm or the right arm or be told that it is okay to cry but that it is important to keep the arm still.

Adolescents (13 to 19 Years of Age)

With adolescence comes independence and autonomy. Peer pressure becomes far more important than the behavior boundaries provided by the caregiver. Adolescents are risk takers and often have no fear of danger or injury. They rarely anticipate consequences and may lack common sense. Privacy and confidentiality should always be respected, and it is wise to separate adolescents from the caregiver when obtaining information and performing the physical examination. Adolescents should be given the opportunity to express their opinions and concerns about their own medical care.

Clinical Features

Recognition of the pediatric patient at risk for decompensation and deterioration is a challenge to the health care provider forced to multitask in a busy ED. Despite the advanced technology available to the provider, the bedside evaluation of the patient is the key component to accurate evaluation and management. The initial assessment of the patient begins with the providers’ examination of respiratory effort and circulation of the skin concurrently with their sense of the child’s acuity, that is, “sick, not sick.”

Pediatric Assessment Triangle

The pediatric assessment triangle (PAT) offers a sensible, orderly approach that can be used to assess children of all ages, identify abnormal cardiopulmonary physiology, and define the

urgency and need for lifesaving interventions. Before touching the patient, one should observe the child from a distance for visual and auditory clues. Figure 164-1 defines the three arms of the PAT: appearance, work of breathing, and circulation to the skin. This brief assessment rarely takes more than 30 seconds and adds to the initial discernment of “sick from well” (Table 164-4).10,11

Appearance

From a distance, one should quickly determine the general appearance of the child. A “hands-off” assessment of infants and young children allows the examiner to gather critical information from a distance before upsetting the child with an invasive physical examination.

The evaluation of appearance can be remembered by the mnemonic TICLS: Tone, Interactiveness, Consolability, Look/Gaze, and Speech/Cry. Is the child interacting normally with the environment? Is the level of consciousness appropriate? Is the patient irritable, somnolent, lethargic, or appropriately responsive? When the brain is not adequately perfused, irritability is usually the first sign. This is followed by alternating irritability and lethargy, which, if left untreated, can progress to coma. Infants can be the most difficult to assess since their ability to interact with their surroundings is limited. The provider may need to rely on parents or caregivers, who can often recognize normal or abnormal behavior for their infant. The glassy-eyed, “nobody home” stare of a septic or brain-injured infant is not difficult to recognize. A high-pitched or cephalic cry is characteristic of any insult to the central nervous system. Simple observation of older children for proper tone, motor movements, and reaction to environmental stimulation is a good assessment of the appearance arm of the PAT. If the child is unusually irritable, allowing the patient to remain with the parent can help differentiate between behavior and pathology. Again, when in doubt a parent or caregiver can confirm whether the behavior is abnormal for the patient. Appearance, when normal, can insinuate that ventilation, oxygenation, and brain perfusion are at least adequate.

Work of Breathing

Assessment of the work of breathing in infants and young children is best done from a distance. Once an infant begins to cry, it is difficult to make any reasonable interpretation of oxygenation and ventilation or to interpret breath sounds. One must listen carefully for audible abnormal airway sounds such as grunting, wheezing, stridor, and snoring. Grunting is an infant’s or child’s way of providing self-administered positive end-expiratory pressure to recruit collapsed or fluid-filled alveoli. The presence of inspiratory stridor alerts the examiner to upper airway obstruction. Muffled, hoarse, or abnormal speech can occur with trauma to the larynx or from a peritonsillar or peripharyngeal abscess. Assessment of the severity of wheezing should be determined by the presence of sounds that occur during both inhalation and exhalation, or just as expiratory sounds, and whether there is a prolonged expiratory phase. Observing for abnormal positioning can help determine the cause and severity of airway obstruction. A child assuming the “sniffing position” is attempting to best position the airway to overcome obstruction. Tripoding is often seen with severe respiratory distress in an attempt to maximize use of the accessory muscles of breathing (Fig. 164-2). The presence of intercostal, supraclavicular, and substernal retractions indicates an increased work of breathing (Fig. 164-3). Infants for the first several months of life may normally have abdominal breathing. Seesaw movements of the chest and abdomen are always abnormal. Nasal flaring and head bobbing can be seen in infants and young children with significantly increased work of breathing (Fig. 164-4).

Figure 164-2. Tripod position in a child with airway obstruction.
Mottling is manifested by areas of vasoconstriction and vasodilation in a random pattern on the skin. It reflects loss of small vessel integrity and may be similar to what is seen in vital organs during multiple organ system failure. Mottling is usually an ominous sign. It is important to not confuse cutis marmorata with mottling in young infants (Fig. 164-5). Cutis marmorata is a lacy marbling of the skin caused by vascular instability. It is a normal finding and is commonly seen in infants in a cool ambient environment. Cyanosis may occur in the late stages of shock or with respiratory failure. Unless the child is cyanotic as a result of chronic primary cardiopulmonary problems or congenital heart disease, the development of cyanosis is an indication of respiratory failure or decompensated shock.

Table 164-5 summarizes how the PAT can be used to interpret specific physiologic abnormalities and the clinical condition of the patient.

**Initial Hands-on Assessment**

Two critical issues should be remembered when interpreting vital signs in children: first, one must remember to use age-appropriate standards (see Table 164-2); second, changes in vital signs over time are far more important than any single recording. A monitored and sleeping infant with an increasing heart rate cannot be ignored. The initial hands-on assessment should be done in an orderly fashion by performing a stepwise assessment of airway,
breathing, and circulation and resolving issues related to each before progressing to the next step.

Assessment of neurologic status or disability provides an opportunity for a more detailed objective measure of the child’s appearance from the PAT. The Glasgow Coma Scale or its pediatric modification provides methods for assessing disability that can be used to monitor changes in mental status over time. The AVPU (alert, verbal, painful, unresponsive) scale is a simple alternative to assess whether the child is alert, responsive to verbal commands, responsive only to painful stimuli, or unresponsive.

Exposure of infants and young children can usually be performed more effectively with the parent’s assistance. One should make every effort to maintain a neutral thermal environment to avoid unnecessary heat loss during the examination. Modesty can be preserved and cooperation can be improved by exposing body parts one area at a time.

Triage

The purpose of triage is to rapidly assess a patient and determine the urgency of evaluation and management. A number of triage scores have been devised, including the recently developed Canadian Pediatric Triage and Acuity Scale. This triage tool uses a five-level system. Table 164-6 uses a similar triage tool to list the 10 most common signs, symptoms, or problems categorized as triage level I in a busy inner-city ED in the United States. A triage level I patient is defined as one in shock or respiratory failure, unresponsive, or with absent or unstable vital signs. Traumatic injuries rank first for triage level I visits and rank third for triage level II visits. The second most common cause for a triage level I ED visit is seizures, which represent 16% of all triage level I visits. Respiratory failure is responsible for nearly 10% of all triage level I ED visits, and respiratory distress is the most common cause of triage level II visits.

Table 164-7 lists the 10 most common causes for triage level II visits. A triage level II patient is one who is considered to be an emergency with a potential threat to life, limb, or function; one who is lethargic, with significant respiratory distress; or one with severe pain. A level II patient requires physician assessment within 15 minutes of arrival to triage.

Clinical Interview

The initial contact with the child and parent will often determine the ultimate level of cooperation received and parent satisfaction with the visit. Parents who bring children to an ED for care usually perceive that their child has an emergency. Treating a family with respect, gentleness, and kindness goes a long way in ensuring a trusting patient-doctor relationship. If the family has been waiting a long time to see the doctor, start the conversation with a simple apology that expresses regret for the long wait. Introducing oneself to both the parents and child will facilitate a relaxed atmosphere for the interview.

Toddlers and early school-age children may be expected to say little during the interview process, but they should be allowed to provide answers to questions when appropriate. In an emergency setting, the chief complaint and present illness are the main focus for information gathering, but the past,
-focused “SAMPLE” History

</tr>
</thead>
</table>

family, and social history pertinent to the child’s condition must also be explored. It is wise to not begin the interview with “What’s the problem?” Parents do not like to consider their children or their conditions as “problems.” A better approach would be “What brings you and your child to the emergency department today?” The “SAMPLE” mnemonic may be used to systematically obtain a focused history (Box 164-1). Signs and symptoms that describe the onset and nature of the chief complaint should be detailed. Allergies or drug reactions are recorded with information describing the characteristics of the reaction. Medications that the patient is currently taking are recorded, including the time and amount of the last dose. Past medical problems and special health care needs are detailed, including information about the pregnancy, labor and delivery, and current immunization status. Knowledge of the last food and liquid given is important if sedation, analgesia, airway management, or surgery is necessary. Events leading up to the injury or illness should be recorded. Gentle and soothing conversation throughout the physical examination often facilitates information gathering and reduces anxiety. The history is generally obtained while performing the secondary assessment.

**Physical Examination**

In infants and young children, the physical examination is not a stepwise process. It is neither a head-to-toe nor a toe-to-head evaluation. The examination should be performed in the least traumatic fashion by leaving painful or frightening components until the end and concentrating on high-value components initially. Children in late infancy through the toddler age should be left in the caregiver’s lap during the majority of the examination.

**Specific Disorders**

**Trauma**

The initial assessment of the injured pediatric patient starts with a primary survey that includes careful assessment of the airway, adequacy of oxygenation and ventilation, as well as a search for signs of circulatory compromise. Once life-threatening abnormalities are identified and appropriate resuscitation efforts are begun, a careful and detailed secondary trauma survey is necessary to identify subtle but potentially life-threatening injuries. A systematic approach to pediatric trauma that includes a continuum of care from first responders through ED stabilization, interfacility transport, and definitive care will save lives.12

Attention to assessment of the cervical spine is a critical part of pediatric assessment. Because of the elasticity of the cervical spine in young children, spinal cord injuries without radiographic abnormalities (SCIWORA) can occur. These injuries result in ligamentous instability, which if ignored may result in significant morbidity or mortality. A history of neck pain, paresthesias, numbness, tingling, or focal neurologic findings must not be ignored even if cervical spine films are normal.13 Because most out-of-hospital emergency medical systems require out-of-hospital providers to transport patients in complete spinal immobilization, it is important to obtain information from the transport professionals. Was the immobilization simply a precautionary measure by protocol? Was the child up, walking, and moving the neck before immobilization? Was there any history of pain, paresthesias, or evidence of neurologic injury? Such information can be helpful in determining whether the child needs radiographic imaging or can be clinically cleared from cervical spine immobilization. The decision to clinically clear a patient from immobilization can be considered if the patient is awake, alert, and cooperative with no distracting injuries and denies cervical spine tenderness. If at any time during the examination the patient complains of pain or has midline cervical tenderness, clinical clearance cannot be completed.

As the secondary trauma survey is systematically performed, continued attention to the PAT and primary survey is critical to identify ongoing bleeding or progressing respiratory problems. A pale trauma victim should have vascular access and blood available before or during the secondary survey.

Intentional injuries to children still result in more than 1200 deaths per year. Because these injuries are most commonly associated with blunt trauma, it is possible that no external evidence of injury will be apparent.14 When historical indicators suggest possible child abuse, consultation with child protective services is mandatory. Box 164-2 lists historical indicators that should alert the heath care provider to the possibility of child abuse.15 Examination of the skin for burns or bruises consistent with child abuse should be a part of any trauma survey. Box 164-3 summarizes bruises typically found in abused infants and children. See Chapter 64 for a more extensive discussion of these issues.

**Box 164-2** Historical Indicators of Child Abuse

- Unexplained delay in seeking medical care.
- History does not explain the injury.
- History changes with time.
- History is not consistent with the child's developmental abilities.
- Child has “magical” injuries.

**Box 164-3** Bruises Suggestive of Child Abuse

- Any unexplained bruising in an infant under 9 months of age.
- Multiple bruises of different ages.
- Pattern injuries:
  - Handprints
  - Belt marks
  - Cord loop marks
  - Linear marks from rigid objects
  - Bite marks
- Unusual distribution of bruises:
  - Neck
  - Groin
  - Inner aspect of thigh
- Restraint marks on wrists or ankles.
serious intracranial pathology and are never seen in patients unresponsive because of metabolic derangements. A unilaterally dilated pupil is secondary to increased intracranial pressure from mass lesions causing uncal compression on the third cranial nerve or due to direct ocular trauma. With significantly increased intracranial pressure, transtentorial herniation will increase pressure on the brainstem and result in asymmetrical pupils that become fixed and dilated. One should observe closely for equality of extraocular movements, nystagmus, and deviation of the eyes at rest. Funduscopic examination is helpful in identifying papilledema and retinal hemorrhages.

Assessment of motor movements including strength and tone is an important part of the secondary assessment for altered consciousness. One should observe closely for symmetry of movements as the absence of symmetry should signal the possibility of stroke and the presence or absence of abnormal posturing should alert the provider to the possibility of intracranial pathology and/or seizure.

**Shock.** Patients with trauma, sepsis, cardiac problems, diabetic ketoacidosis, diarrhea, vomiting, and ingestion of toxic substances may arrive at the ED in shock. The secondary survey will help differentiate causes of the shock state. Assessment of four organ systems in systematic fashion will help determine the etiology and severity of the shock and monitor response to treatment. The heart is the first organ to respond to a shock state and does so with an increased rate. Cardiac output is a function of stroke volume and heart rate, and when stroke volume decreases for any reason, the heart rate will increase. Careful examination of the heart by listening closely for a gallop rhythm, murmurs, indistinct or muffled heart sounds, or any dysrhythmia will help identify cardiogenic shock as the cause. The presence of these signs with development of hepatomegaly, especially after the administration of intravenous fluids, can also indicate the presence of cardiogenic shock. Tachycardia may be absent in patients with distributive shock. In the late stages of decompensated shock, bradycardia will occur as the shock progresses and can herald cardiopulmonary failure.

The second organ to respond to shock is the skin. In addition to the manifestations covered in the PAT, one should observe for skin temperature and signs of dehydration. The reverse thermometer sign can be of assistance in roughly judging the degree of hypovolemic shock. The examiner assesses skin temperature by running the fingers up the extremity to determine the point of cool/warm demarcation. During resuscitation, as reperfusion of the skin occurs, this point of warm/cold demarcation progresses peripherally. With early septic shock, the skin may appear warm and flushed. One must look closely for signs of dehydration, including tenting of the skin, a hollow-eyed appearance, or dry mucous membranes, which may suggest dehydration and hypovolemic shock. Capillary refill must be measured at or above the level of the heart to avoid erroneous results from venous flushing. In a neutral thermal environment, capillary refill longer than 2 seconds will be present in all forms of shock.

The third organ that objectively responds to the shock state is the brain. Irritability or a decrease in mental status is consistent with progressing shock.

The lungs respond to shock with tachypnea and hyperpnea. Hypovolemic shock will often be manifested as effortless tachypnea when the patient has become acidotic. Cardiogenic shock, distributive shock, and septic shock may also give rise to increased work of breathing, crackles, or wheezing (or any combination of the three).

Close and repeated monitoring of these four organ systems must be continued throughout the secondary survey and stabilization processes.

**Children with Special Health Care Needs**

Children with special health care needs account for a large number of emergency and urgent ED visits. In a child with developmental delay or significant neurologic problems, clinical assessment can be difficult and routine assessment tools may be limited in their usefulness. The caretaker is usually quite experienced and can often provide valuable information to assist in assessment. A behavior change recognized by the caretaker may be the only clue to a potentially serious illness or complication. For example, children with life-sustaining hardware such as ventriculoperitoneal shunts commonly come to the ED with nonspecific findings such as vomiting and headache, and change in behavior may be the only clue leading to an accurate diagnosis.

It is important to engage the parent to assist with baseline information and to seek specialty consultation from providers who are familiar with children who have special health care needs.

**Noninvasive Monitoring**

Noninvasive monitoring techniques such as oxygen saturation and end-tidal carbon dioxide measurements have become a routine part of pediatric assessment for a variety of illnesses and injuries. Pulse oximetry provides a valuable noninvasive and continuous measurement of arterial hemoglobin oxygen saturation, which has rapidly become a new “vital sign” for many illnesses. The role of pulse oximetry in monitoring children with respiratory distress and failure has been well defined. The use of pulse oximetry in children with cardiopulmonary problems is a valuable assessment tool and helps the clinician titrate the need for oxygen supplementation and respiratory support.

End-tidal CO₂ measurement is a noninvasive method for monitoring a variety of critically ill children that helps avoid repeated blood gas analysis. Studies have demonstrated that analysis of exhaled end-tidal CO₂ can be used to monitor respiratory failure, accurate endotracheal tube placement, and perfusion to peripheral tissues during the resuscitation of patients in shock. Measurement of end-tidal CO₂ and pulse oximetry can provide valuable assistance in monitoring children in both shock and respiratory failure. It is also a critical component of assessing correct placement of a tracheal tube after intubation has been performed.

**The Pediatric-Ready Emergency Department**

ED preparedness for the care of children is a special need that requires limited additional resources, but significant professional support and advocacy from both physicians and nursing staff. It is quite clear that the majority of hospitals with EDs will serve as pediatric receiving facilities for emergency care independent of size, volume, or availability of comprehensive resources. Hospitals without all the necessary resources must clearly be prepared to stabilize critical pediatric illnesses and injuries within their limitations and ensure timely transfer to facilities with available necessary resources. Guidelines for preparedness for the care of children in the ED are available. The availability of protocols and policies that ensure timely transfer of critically ill and injured patients after stabilization is a part of the pediatric assessment process.
### KEY CONCEPTS

- The physical and developmental stages of growth in pediatric patients provide challenges to the assessment of children in crisis.
- An understanding of age-related developmental issues and differences is important for performing an adequate pediatric assessment.
- One must establish rapport with pediatric patients to get cooperation in performing the examination.
- Abnormal vital signs always require explanation and resolution.
- The PAT provides a rapid assessment of severity and physiologic status and will provide a road map for the initial assessment of all pediatric patients.
- Continuing close monitoring and reassessment, especially following any intervention, is a key component to the evaluation and management of the ill or injured child.
- A neutral thermal environment should be maintained during the physical examination to avoid heat loss in infants who are critically ill.
- The presence of a difficult airway can be assessed in seriously ill or injured children by determining whether they are able to open their mouth wide enough for visualization of the uvula and normally extend and flex their neck.
- With special needs children, the caregiver can assist in determining baseline status.
- Beware the pale child: Pallor is a consistent and objective early sign of shock that cannot be ignored, especially in those with blunt trauma.
- Cervical spine: A large head with an elastic cervical spine may result in SCIWORA. Patients with this condition may not have any neurologic deficits, and cervical spine images may be normal. A history of transient paresthesia, numbness, tingling, or any focal neurologic findings, even if radiographs are normal, should be interpreted in this light and clinical clearance from immobilization should be delayed until further evaluation is performed.

*The references for this chapter can be found online by accessing the accompanying Expert Consult website.*
Fever is the most common presenting chief complaint in pediatric patients presenting to the emergency department (ED), accounting for up to 20% of ED visits. Most cases of fever are viral in origin, benign in course, and resolve spontaneously. Fever tends to be of a higher clinical importance in younger children as they are immunologically immature and incompletely vaccinated. Management of children presenting to the ED varies dramatically depending on the age of the child with the following common, albeit arbitrary, divisions (0–28 days, 0–2 months, 2–3 months, 3–6 months, 6–36 months, 3 years to adulthood). These divisions reflect differing immunologic and vaccination milestones as well as the spectrum of age-specific pathogens.

### PERSPECTIVE

**Definitions and Epidemiology**

Fever is defined as any elevation in body temperature equal to or above 38.0°C and typically is the result of infection. The most reliable method to measure temperature is via a rectal thermometer, particularly in high-risk groups such as infants 0 to 3 months of age as axillary, oral, or tympanic thermometers are unreliable in this age group. The rectal route should not be used in patients who are potentially immunocompromised (i.e., children with fever who are receiving cytotoxic chemotherapy) due to the risk of mucosal damage, bacteremia, or transmission of infection. The cutoff for a clinically significant fever (i.e., one that triggers a laboratory evaluation) varies with the age and immunologic status of the child. A rectal temperature of 38.0°C is generally considered to be a clinically significant fever in an infant less than 3 months old, necessitating a thorough laboratory workup, whereas a toddler with a temperature of 39.5°C and an upper respiratory infection may not need any workup beyond a thorough history and physical. Fever is to be distinguished from hyperthermia, which is an elevation in the body’s “set point.” Causes of hyperthermia include bundling, heatstroke, salicylate ingestion, malignant hyperthermia as a complication of inhalational anesthetics, and elevation in temperature secondary to hypothalamic central nervous system (CNS) damage.

The cause of fever varies depending on the age of the child (Table 165-1). The vast majority of pediatric fever is due to infections, and the vast majority of infections are attributable to a viral source. Upper respiratory infections, viral gastroenteritis, croup, bronchiolitis, stomatitis, roseola, infectious mononucleosis, and varicella are all known causes of fever. Most viral illnesses are benign and self-limited, but infection with herpes simplex virus (HSV) at any age, or respiratory syncytial virus (RSV), particularly in the first month of life, can lead to significant morbidity and mortality.

Bacterial disease is also an important cause of fever in children. Serious bacterial illness (SBI) is typically defined as the presence of pathogenic bacteria in a previously sterile site and includes urinary tract infection (UTI), bacteremia, meningitis, osteomyelitis, bacterial gastroenteritis, bacterial pneumonia, cellulitis, or septic arthritis. Studies have found the risk of SBI in febrile infants less than 3 months of age to be between 6 and 10%, with children less than 28 days of age having the highest incidence. Pathogens change during early infancy, with vertical transmission of organisms such as group B Streptococcus, Listeria monocytogenes, and HSV being more common in neonates. By 1 to 2 months of age, organisms such as Streptococcus pneumoniae, Neisseria meningitidis, and urinary pathogens (Escherichia coli or Enterococcus) become more common. In all children less than 3 months of age, the urinary tract is the most common site of infection, followed by bacteremia and meningitis. UTIs are more common in white children, particularly females, when compared with other races and is of higher prevalence in patients in whom no source for infection is found and who have higher temperatures (i.e., >39.0°C).

Children under the age of 3 months may present with an apparent viral syndrome and still harbor serious bacterial illness. Levine and colleagues studied 1248 infants less than 60 days of age who had temperatures above 38.0°C. Of these children, 22% were positive for RSV. Although, overall, children with documented RSV had a lower incidence of concomitant SBI than those without RSV (12.5 vs. 7%), there was no significant difference in rates of SBI in children less than 28 days of age (14.2% in RSV-negative neonates vs. 10.1% in RSV-positive infants). Most of the bacterial infections were UTIs.

Older children 3 to 36 months of age with recognizable viral syndromes (e.g., croup, bronchiolitis, varicella, stomatitis) generally have a very low incidence of bacteremia. Greene and coworkers found that among 1347 patients with fever above 39.0°C who had a recognizable viral syndrome, the risk of bacteremia was 0.2%.

Occult bacteremia describes the presence of pathogenic bacteria in the bloodstream of a well-appearing febrile child in the absence of a focus of infection and was first described as a clinical entity in the 1970s. The term typically refers to children 3 to 36 months of age who are highly febrile (>39.0°C) but appear well. Prior to the adoption of the conjugate vaccines
against *Haemophilus influenzae* type b (HIB) and *S. pneumoniae*, the incidence of bacteremia in this population was approximately 5%.\textsuperscript{7,8} Vaccination has proven remarkably effective, nearly eradicating HIB as a significant pathogen and greatly reducing the burden of pneumococcal disease (Fig. 165-1).\textsuperscript{9–11} Currently, the rate of occult bacteremia is below 1%, with pathogens such as *N. meningitidis* becoming proportionally more prevalent. Continued surveillance is ongoing to ensure that there is not a rise in invasive disease caused by nonvaccine serotypes. Urinary pathogens continue to be an important source of bacterial illness in infants and children, occurring in 2% of febrile children less than 5 years of age. Rates are highest in males less than 6 months of age (2.7%) and females less than 12 months of age (6–8%).\textsuperscript{12,13}

Bacterial illness in school-aged children and adolescents includes focal infections such as streptococcal pharyngitis, cellulitis, and pneumonia, as well as bacteremia and meningitis. *N. meningitidis* has a bimodal distribution, with the highest incidence in children under 12 months of age (9.2/100,000 population). A second peak occurs during adolescence, when the rate of illness is 1.2/100,000 population, with a significant proportion of cases occurring in college students who reside in a dormitory setting (3.2/100,000 population).\textsuperscript{14}

Although much less common than viral or bacterial infection, fever can also be a presenting sign of autoimmune diseases such as juvenile rheumatoid arthritis or Kawasaki disease (KD). CNS lesions such as brain tumors also can infrequently present with fever.

### DISTINGUISHING PRINCIPLES OF DISEASE

#### Pathophysiology

The body’s ability to fight infection varies with age. Maternal antibodies confer some protection after birth, but the infant’s
immune system, particularly T-cell function and the ability to mount an immunoglobulin G response to infection, is initially inadequate. The immature neonatal immune system as well as exposure to certain pathogens during the birthing process (e.g., group B Streptococcus, Chlamydia trachomatis, Neisseria gonorrhoeae) places the newborn at particular risk for serious bacterial illness. Young infants are also at risk for disseminated infection as they are unable to mount the immune response needed to prevent a localized infection from spreading. Thus, a simple cellulitis, mastitis, omphalitis, or, rarely, gonococcal eye disease can lead to sepsis or focal seeding of the CNS, making aggressive evaluation and treatment of such infections prudent. Immune function improves over the first 2 to 3 months of life, but the risk of SBI does not diminish appreciably until the primary series of vaccinations against HIB and pneumococcus is completed (6 months of age).

**History**

When dealing with a febrile child, history taking should focus on the length of illness, presence of localizing symptoms, as well as any pertinent past medical history. In infants less than 28 days of age, birth history, particularly the presence of potentially transmittable maternal infection (HSV or group B Streptococcus), is critically important. Immunization status, sick contacts, use of antipyretics prior to evaluation, and prior use of antibiotics are also important historical items. Defervescence after acetaminophen administration has not been shown to reliably exclude bacteremia.15 Prior antibiotic use may mask the classic findings in diseases such as meningitis. Cough and congestion may suggest pneumonia or viral upper respiratory infection, whereas a harsh, barking, or seal-like cough is often a predominant complaint in viral laryngotracheitis (croup). Parents may report vomiting and diarrhea as a component of gastroenteritis or the presence of sore throat and lymphadenopathy with viral or streptococcal pharyngitis. A history of decreased oral intake or decreased urine output is frequently a complaint in gastroenteritis but may also be seen in patients with stomatitis as the painful aphthous ulcerations in the mouth make fluid intake difficult. Any history of lethargy, irritability, or altered mental status can be seen with severe dehydation but raises the specter of meningitis or encephalitis. A history of rash is seen in many viral illnesses such as roseola, but also may be seen in life-threatening conditions such as meningococemia, Rocky Mountain spotted fever, or toxic shock syndrome (TSS). Complaints of headache and neck pain (meningitis or encephalitis) or ear pain (otitis media) are also important historical points.

**Physical Examination**

The physical examination of the febrile child should begin with a complete set of vital signs, including pulse oximetry. Hypoxia or significant respiratory distress manifested by tachypnea, grunting respirations, nasal flaring, or retractions may accompany sepsis or pulmonary infection. Stridor can be seen with croup but also can be seen with retropharyngeal abscess, epiglottitis, or bacterial tracheitis. Signs of shock such as hypotension or poor peripheral perfusion should be noted. Children typically mount a tachycardic response to fever, and hypotension is often a late and dire finding. Tachycardia is often due to the fever itself, but tachycardia out of proportion to the degree of fever is often seen in other conditions such as myocarditis, hypovolemia, or dehydration. Greenes and colleagues found that in infants less than 12 months of age, heart rate increases linearly by 9.6 beats/min with each 1°C increase in body temperature; however, caution must be exercised in attributing tachycardia to fever alone.16 Once oxygenation, ventilation, and perfusion have been assessed and deemed adequate, the physical examination should focus on a thorough search for focal infection. It should be noted that in young infants, particularly those less than 3 months of age, as well as in children who lack immunocompetence, fever may be the only presenting sign of serious illness, including meningitis. The physical examination in this age group is sufficiently insensitive to exclude serious bacterial illness, and clinicians should not be falsely reassured by a normal physical examination in small children.

**Ancillary Testing**

There are numerous laboratory and radiographic studies that can be used to evaluate the febrile child. Generally, testing should be directed at identifying the source of infection or evaluating for complications. Several guidelines exist for the evaluation of febrile children, although there is marked variation in adherence to these guidelines. Pantell and associates found that office-based practitioners followed published guidelines only 42% of the time when evaluating febrile children.17 Clinicians with less experience and those based in the hospital tend to order more tests compared with more experienced clinicians and those practicing in an office setting.

**White Blood Cell Count**

An elevated white blood cell (WBC) count (>15,000/mm³) can be an indicator of bacteremia but is also present in many viral illnesses. Leukopenia (<5,000/mm³) can also be a sign of serious bacterial disease or early sepsis. An elevated WBC count is classically associated with pneumococcal disease, while infection with N. meningitidis and H. influenzae may be present even with normal WBC counts. Lee and colleagues found that the rate of pneumococcal bacteremia increased from 0.5% in highly febrile children (>39.0°C) with WBC between 10,000 and 15,000/mm³ to 3.5% if the WBC was 15,000 to 20,000/mm³, and up to 18% with WBC above 30,000/mm³.18

The WBC differential has also been used to risk stratify febrile children in various models, with an increase in polymorphonuclear leukocytes (PMNs) and immature band forms increasing the risk of bacterial disease. A rise in PMNs is also seen early in some viral infections. An absolute neutrophil count (ANC) greater than 10,000/mm³ suggests increased risk of pneumococcal bacteremia in febrile children; 0.8% for children with an ANC less than 10,000/mm³ versus 8% for children with an ANC above 10,000/mm³.19

**Blood Culture**

A blood culture is a useful diagnostic test when bacteremia is suspected. In infants and children, blood should be obtained after sterile preparation of the skin, which includes an alcohol preparation and swabbing of the skin with povidone-iodine solution, which is then allowed to dry. Many centers obtain blood for culture during intravenous catheter placement after sterile preparation of the skin has been performed. This technique has the advantage of eliminating the second venipuncture solely to obtain blood for culture, although the rates of contamination using this technique have been shown to be higher in children (9.1 vs. 2.8%).25 The risks of contamination must be weighed against the risks and ability to obtain blood via a separate venipuncture. The yield of a single blood culture in infants and small children is actually quite good. Routinely sending more than one sample is generally not needed, and often accurate detection of bacteremia occurs even if only 0.5
to 1 mm of blood is obtained. The advent of automated blood culture systems led to the identification of true pathogens more quickly than traditional methods, often within 24 hours. Pathogens isolated in the first 24 hours are more likely to be true pathogens than bacteria isolated after 24 hours.21

**Urinalysis and Urine Culture**

Urinary tract infections are common causes of bacterial illness in febrile children. Accurate documentation of UTI is imperative both as a means to diagnose the cause of a fever as well as to identify those infants who need follow-up radiographic imaging (typically voiding cystourethrogram [VCUG] and/or renal ultrasound) to exclude anatomic abnormalities that will predispose them to further infection. The only reliable method to obtain urine in a non-toilet-trained child is through bladder catheterization or suprapubic aspiration. Bag collection of urine is notoriously unreliable as up to 85% of positive cultures from bag specimens will be false positives (defined as a culture growing a single organism with <105 colony forming units [CFU]/mL or a mix of two or more organisms), which then places these children at risk for unneeded costly, potentially painful, and expensive follow-up diagnostic testing. Obtaining urine via a clean catch specimen is appropriate for older toilet-trained children.

Urinary tract infection is defined as the combination of bacteriuria and pyuria. Bacteriuria in the absence of WBCs on microscopic examination represents asymptomatic bacteriuria. Urine is typically analyzed using a dipstick followed by microscopic analysis of a centrifuged specimen of urine. Hoberman and colleagues describe the test characteristics of an “enhanced” urinalysis, which is examination using a hemocytometer of an unspun specimen of urine for pyuria (defined as >10 WBCs/high-power field [hpf]) or presence of any bacteria/hpf in a Gram’s stain of unspun urine. They report a negative predictive value of 99.8%, perhaps making urine culture unneeded if pyuria and bacteriuria are absent using the enhanced urinalysis method.22 Many centers are not using this enhanced method. Because dipstick and microscopic analysis have lower sensitivities, most experts recommend sending urine for culture in high-risk groups (febrile girls <12 months of age, uncircumcised boys <12 months of age, and circumcised boys <6 months of age).

A positive urine culture is defined as the growth of greater than 10,000 CFU/mL from urine obtained from a catheterized or suprapubic sample. In older children, where urine is typically obtained from a clean catch specimen, a higher threshold of greater than 100,000 CFU/mL is typically employed.

**Lumbar Puncture**

A sample of cerebrospinal fluid (CSF) should be obtained from any child with signs and symptoms of meningitis. Fluid should be obtained using the smallest noncutting spinal needle possible (typically a 22-gauge spinal needle) and sent for cell counts, manual differential, Gram’s staining, culture, and measurement of CSF protein and glucose. Meningocencephalitis due to HSV is a potential cause for fever, particularly in children, and if suspected, sending CSF for HSV polymerase chain reaction testing is indicated. The CSF in bacterial meningitis typically contains greater than 1000 WBCs/mL, although there is considerable overlap in the CSF profile of bacterial and viral meningitis, making a determination of viral or aseptic meningitis difficult based on CSF parameters such as cell count, protein, and glucose; thus, CSF culture of a pathogenic bacteria is the gold standard. A prediction rule has recently been developed and validated to differentiate bacterial from aseptic meningitis.23 Children who lack all of the following criteria have a low risk (0.1%) of bacterial meningitis: positive CSF Gram’s stain, CSF ANC of at least 1000 cells/µL, CSF protein of at least 80 mg/dL, peripheral blood ANC of at least 10,000 cells/µL, and a history of seizure before or at the time of presentation. This may obviate the need for empirical antibiotic therapy and hospital admission in some children who are at low risk for bacterial meningitis.

Contraindications to lumbar puncture include cellulitis over the proposed site of puncture, cardiopulmonary instability, bleeding diathesis, focal neurologic deficits, and signs of increased intracranial pressure, including papilledema. In these patients, lumbar puncture should be deferred until the child is stable and blood should be obtained for culture, recognizing that up to 50% of children with meningitis will not have bacteremia.24

CSF contaminated by blood, or a traumatic lumbar puncture, can make interpretation of cell counts and differentials difficult. In these cases, fluid should be obtained for Gram’s stain and culture and the child treated presumptively for meningitis until culture data are available. Nigrovic and coworkers have shown that risk factors for a traumatic lumbar puncture include operator experience, excessive patient movement during the procedure, advancing the needle with the stylet in place, and lack of local anesthesia.25

**Stool Studies**

Stool studies are indicated in patients in whom bacterial gastroenteritis may be a cause of a fever. A stool guaiac for blood should be performed as well as a Gram’s stain for WBCs. Presence of either in the febrile child should trigger a culture of stool for the presence of *Salmonella*, *Shigella*, *Campylobacter*, enterotoxigenic *Escherichia coli*, and *Yersinia* species. Patients with sickle cell disease are at particular risk for focal complications such as osteomyelitis from *Salmonella* infection.

**Chest Radiography**

Chest radiographs may be useful in the workup of the febrile child and are indicated when hypoxemia, respiratory distress, tachypnea, or focal findings on lung examination are present. Children younger than 6 months may present with tachypnea as the sole findings of bacterial pneumonia. Truly occult pneumonia can also occur, particularly in the highly febrile child (39.0°C) without apparent source of fever. Bachur and associates found that the 26% of children with fever above 39.0°C and WBC counts greater than 20,000 had radiographic evidence of pneumonia.26 Of note, this study was done in the era prior to the conjugate pneumococcal vaccine.

**Rapid Viral Antigen Testing**

Many clinical laboratories have the ability to perform rapid viral antigen testing for such common pediatric viral illnesses as influenza A and B and RSV. The presence of a viral “source” for the fever in an ill child may obviate the need for expensive, painful, and lengthy diagnostic workups for bacterial processes. Bonner and colleagues evaluated the impact of physician knowledge of the presence of a positive rapid influenza assay result.27 The investigators studied 391 patients ages 2 months to 21 years who presented with classic signs and symptoms of influenza. Of these patients, over half had positive rapid assays for influenza and the investigators noted that significantly fewer laboratory and radiographic studies were ordered if the treating clinician was aware of these results. There were also fewer antibiotics prescribed.
RSV is also a frequent cause of fever in children. Levine and coworkers found that in febrile children less than 60 days of age, the presence of RSV reduced the risk of concomitant serious bacterial illness (12.5 vs. 7%), although in children under the age of 28 days, the risk reduction was not statistically significant (14.2 vs. 10.1%). Most of the serious bacterial illnesses in this study of RSV-positive children were UTIs.

### SPECIFIC DISORDERS

#### General Approach to the Febrile Infant and Child

The initial approach to any child with a febrile illness is a rapid assessment for evidence of cardiopulmonary compromise or shock. Significant respiratory distress, hypoxemia unresponsive to supplemental oxygen, or altered mental status may necessitate intubation via rapid sequence induction and mechanical ventilation. Evidence of shock (poor perfusion, hypotension, altered mentation) should be aggressively treated with fluid resuscitation. An intravenous or intraosseous line should be placed and the initial resuscitative fluid should be 20 mL/kg of isotonic crystalloid. This should be repeated to a total of 60 to 100 mL/kg if signs of hypovolemia persist, after which the use of vasopressor therapy (dopamine 1–20 µg/kg/min or norepinephrine 0.1–3 µg/kg/min titrated to blood pressure) should be considered.

Every effort should be made to obtain appropriate specimens for culture (blood and urine), even in the critically ill child prior to antibiotic administration. Lumbar puncture may be deferred in the critically ill child until stabilization occurs. Empirical antibiotic therapy should be directed at the most likely causative organisms based on age. Sterilization of the CSF occurs quickly once antibiotic administration has been initiated: within 15 minutes to 2 hours in patients with meningococcal meningitis and within 4 to 10 hours in patients with pneumococcal meningitis.

#### Serious Bacterial Illness

##### Infants 0 to 28 Days of Age

Children presenting with fever above 38.0°C who are less than 28 days of age are at particularly high risk for bacterial illness, with rates as high as 12% quoted in the literature. Often, fever is the only manifestation of potentially life-threatening disease, and other signs and symptoms may be exceedingly subtle, and this has led to an aggressive approach to diagnostic testing, empirical antibiotic therapy, and hospitalization in this age group, even if the child is well-appearing.

Often, children in this age group present with nonspecific complaints such as irritability, lethargy, poor feeding, or grunting. Besides fever, other signs of serious illness include a bulging fontanel, mottled extremities, petechiae, or tachypnea. Bacterial pathogens in this age group include group B Streptococcus, L. monocytogenes, N. meningitidis, S. pneumoniae, and E. coli. Viral pathogens, including RSV and HSV, are also important considerations. Neonatal HSV infection in particular carries a high degree of morbidity and mortality and should be considered in any febrile neonate with a maternal history of genital herpes, who is ill-appearing, who presents with fever and seizure, who has cutaneous vesicles on physical examination, or who has evidence of transaminitis or coagulopathy. HSV meningoencephalitis should also be considered in patients with fever and CSF pleocytosis but a negative CSF Gram’s stain. The risk period for HSV disease tends to be between 2 and 12 days of age (Fig. 165-2). Other noninfectious causes of a septic-appearing neonate include the acute salt-wasting crisis associated with congenital adrenal hyperplasia and undiagnosed ductal-dependent congenital heart disease.

Because of the high risk of bacterial pathogens and the difficulty in clinically assessing children younger than 28 days of age, these patients require an aggressive diagnostic evaluation, including a complete septic workup. This consists of a complete blood count (CBC), blood culture, urinalysis and urine culture, and lumbar puncture. Lumbar puncture is indicated even in the presence of a UTI due to the risk of concomitant meningitis. All children in this age group should be admitted to the hospital on empirical antibiotics until culture data become available. Appropriate parenteral antibiotic regimens include ampicillin (100 mg/kg/24 hours divided every 6 hours) plus either gentamicin (5 mg/kg/24 hours divided every 8 to 12 hours) or cefotaxime (150 mg/kg/24 hours divided every 8 hours). Ceftriaxone should be avoided in infants under 28 days of age because of a theoretical risk of inducing acute bilirubin encephalopathy as ceftriaxone causes bilirubin to displace from its protein binding sites. Empirical acyclovir should be added if risk factors for HSV disease exist (60 mg/kg/24 hours, divided every 8 hours).

##### Infants 29 to 90 Days of Age

Although there is a relative consensus as to the evaluation and management of febrile infants younger than 28 days of age, there is debate about the appropriate workup for the slightly older febrile infants. Ill-appearing children of any age should have a complete sepsis evaluation performed and be admitted to the hospital on empirical antibiotic therapy. Appropriate antibiotic therapy for high-risk children would include coverage of neonatal pathogens such as Listeria monocytogenes and group B streptococci as well as coverage against H. influenzae, N. meningitidis, and S. pneumoniae. Ampicillin, 50 to 100 mg/kg every 6 hours, plus cefotaxime, 50 mg/kg every 8 hours parenterally, is one alternative. Vancomycin, 40 to 60 mg/kg intravenously (IV) every 6 to 8 hours, should be considered if S. pneumoniae resistant to penicillins and cephalosporins is suspected. Various strategies (herein referred to as the Rochester, Philadelphia, and Boston criteria) for the evaluation of well-appearing children have been reported, compared, and retested in the literature. Each strategy has unique features, including the definition of fever (38.0 vs. 38.2°C), study population (0–3 months of age, 1–2 months of age, and 1–3 months of age), the clinical and laboratory variables studied, and disposition (hospitalization with/without antibiotics or outpatient treatment with/without antibiotics). Each strategy seeks to
identify a set of low-risk criteria that, if met, will allow for less aggressive treatment or withhold empirical antibiotic therapy. The three main strategies are highlighted in Table 165-2. Baraff synthesized the recommendations of the Rochester, Philadelphia, and Boston criteria into an algorithm for the management of the previously healthy febrile infant 29 to 90 days of age (Fig. 165-3). To be low risk, the child had to have been previously healthy with an uncomplicated nursery stay, be nontoxic clinically, and have no focal source of bacterial infection. Low-risk laboratory criteria in this schema included a normal WBC count (between 5000 and 15,000 WBCs/mm³), less than 1500 bands/mm³, a normal urinalysis (negative Gram’s stain and <5 WBCs/hpf), and a negative CSF Gram’s stain and cell counts (<8 WBCs/mm³), if obtained. When diarrhea was present, less than 5 WBCs/hpf was the threshold for low risk. Once deemed low risk by these criteria, two options are available to the clinician based on the Philadelphia and Boston criteria. The first management strategy calls for a CBC, blood culture, urinalysis, and urine culture. Once these studies were obtained, the child could be discharged with close outpatient follow-up. The second option, based on the Boston criteria, calls for a complete sepsis evaluation including lumbar puncture, followed by empirical treatment with ceftriaxone (50 mg/kg IV or intramuscularly [IM]) and reevaluation within 24 hours. The important difference between these two strategies is that empirical antibiotics should not be administered unless a complete sepsis evaluation is performed, including a lumbar puncture. Otherwise, if the child returns for reevaluation and lumbar puncture is performed and CSF pleocytosis is found, pretreatment with antibiotics makes interpretation of culture results difficult. Thus, a child with a possible viral process may be condemned to inpatient admission and 14 days of parenteral antibiotic therapy.

Infants 3 to 36 Months of Age

Fever in children 3 to 36 months of age is incredibly common and most cases represent self-limited viral illnesses. Common causes of fever in this age group include viral upper respiratory infections, croup, bronchiolitis, stomatitis (typically caused by HSV or coxsackievirus), gastroenteritis, roseola, and Fifth’s disease (parvovirus B19 infection). Focal infections such as pharyngitis (group A Streptococcus), septic arthritis, retrophyangyal abscess, meningitis, as well as bacterial pneumonia also become common in this age group. Typically, these focal infections are apparent based on history and physical examination, and diagnostic testing and treatment should be directed accordingly.

The history in this age group should focus on the duration of illness, associated symptoms that may focus the evaluation, and sick contacts. A thorough physical examination is essential to rule out serious focal infection such as meningitis. Young children may demonstrate intractable irritability or lethargy as the sole manifestations of meningitis; furthermore, classic meningial signs such as nuchal rigidity are seen in less than 27% of infants (0–6 months) with bacterial meningitis. Prior research has focused on assessing children in this age group for the presence of occult bacteremia. It was found that a small percentage of highly febrile children (>39.0°C)
3 to 36 months of age were bacteremic. These children were noted to be highly febrile but to lack any localizing signs of infection. No historical or physical examination findings were sufficiently sensitive or specific to identify cases of occult bacteremia, making universal diagnostic testing necessary. A typical workup would include a CBC, blood culture, and empirical antibiotic therapy for children with WBC counts greater than 15,000/mm³. Empirical antibiotics were justified based on studies that revealed treatment with antibiotics prevented focal sequelae of bacteremia such as meningitis and shortened the duration of fever. Prior to the advent of almost universal immunization against *S. pneumoniae*, the rate of occult bacteremia was approximately 3%, and although up to 75% of the time pneumococcal bacteremia resolves without therapy, a small proportion of children develop sepsis or focal infections such as meningitis. Pneumococcal meningitis has a high degree of morbidity and mortality, including permanent neurologic disability, hearing loss, and death.

Since the advent of Prevnar (conjugate pneumococcal vaccine), the number of invasive pneumococcal infections caused by vaccine-serogroup isolates among eight U.S. children’s hospitals has decreased more than 75% among children less than 24 months of age. Due to the decline in invasive pneumococcal disease brought on by vaccination, the cost-effectiveness of mandatory blood testing has been called into question. Lee and colleagues evaluated the cost-effectiveness of various management strategies including:

- No workup
- Relying on clinical judgment
- Blood culture
- Blood culture plus empirical antibiotics
- WBC count plus blood culture and empirical antibiotics
- WBC count plus selective blood culture for WBC counts greater than 15,000 and empirical antibiotics

They found that at rates of pneumococcal bacteremia greater than 1.5%, obtaining a WBC count plus selective blood culture and empirical antibiotics were the most cost-effective approach. At rates of pneumococcal bacteremia less than 0.5%, strategies that utilized empirical testing and treatment were no longer cost-effective. They concluded that at lower rates of bacteremia, clinical judgment was more useful in selecting out high-risk populations who might benefit from selective testing and treatment.

Although the incidence of pneumococcal bacteremia has declined in infants 3 to 36 months of age due to the aggressive campaign to vaccinate, infants 3 to 6 months of age have not yet completed the primary series of immunizations against *S. pneumoniae* and to a lesser extent, *H. influenzae*. Thus, highly febrile infants (≥39.0°C) without an apparent source on examination should be considered at risk for occult bacteremia and consideration be given to obtaining a WBC count and blood culture as a screen. Empirical antibiotic therapy should be reserved for infants with WBC counts above 15,000/mm³. It is important to note that although the conjugate pneumococcal vaccine contains antigens from the seven most common serotypes that cause invasive disease, there are approximately 90 serotypes that are capable of infecting humans. Continued bacterial surveillance is necessary to ensure that other serotypes do not rise in incidence to fill the void left by vaccination. It should also be noted that no clinical prediction algorithm correctly identifies all patients with meningococcal disease.

Additional signs and symptoms that may suggest meningococcal meningitis are purpuric rash, bandemia, limb pain, and exposure to a person with the disease. An appropriate flow diagram for the workup of febrile infants 3 to 36 months of age is presented in Fig. 165-4.

**Children Ages 3 Years to Adulthood**

The incidence of occult bacteremia decreases after 3 years of age. Focal infections such as streptococcal pharyngitis, septic arthritis, pneumonia, peritonsillar abscess (most often in adolescents), and cellulitis become more common. Viral pathogens are also common, such as infectious mononucleosis. Infection with atypical pathogens such as *Mycoplasma pneumoniae* should also be considered in children presenting with pneumonia. Skin infections secondary to community-acquired methicillin-resistant *Staphylococcus aureus* (CMRSA) are also becoming more common. CMRSA occurs in all age groups but has clustered among such children as wrestlers (associated with contaminated wrestling mats) and football players (infected equipment). This diagnosis should be considered in all children who present with pyogenic skin infection and skin abscesses. Appropriate therapy includes incision and drainage of the abscess cavity and antibiotic therapy with trimethoprim-sulfamethoxazole for patients with large abscesses (>5 cm), with cellulitis, or with fever.

There is also a second peak in incidence of meningococcal disease in adolescent children with an attack rate of 1.2 infections per 100,000 population. As opposed to infants, adolescents with meningococcal infection are more likely to present with meningococcemia (40 vs. 20%), shock at presentation (69 vs. 27%), and have a fatal outcome (22.5 vs. 4.6%). Meningococcal disease typically presents with one of three clinical syndromes: meningitis, bacteremia, or a combination of the two. College students residing in dormitories are at particular risk for infection with attack rates of 3.2/100,000 population. The history in cases of meningococcal infection is often one of rapidly progressive fever, headache, and stiff neck. Shock, altered mental status or frank coma, petechiae or purpura, seizures, and myalgias are also seen. Some of the first signs of meningococcal infection include leg pain, cold hands and feet, or abnormal skin mottingling. Appropriate initial therapy for children suspected of having meningococcal infection is ceftriaxone, 100 mg/kg IV divided over 12 hours.

In January 2005, the Food and Drug Administration approved the meningococcal conjugate vaccine-4 (Menactra) for use in adolescents. This vaccine is a polysaccharide-protein conjugate.
directed against the four serotypes that cause most cases of invasive meningococcal disease in humans. The American College of Immunization Practice recommends vaccination of adolescents at their 11- or 12-year-old well-child check up, and the American Academy of Pediatrics (AAP) has also advised that all college freshmen living in dormitories also be vaccinated. Use of the vaccine is associated with a 67% decrease in invasive disease and a 66% decrease in carriage rates.58

Febrile Seizures

Febrile seizures are a common cause of convulsions in children under the age of 5 years. They are defined as a seizure accompanied by fever without the presence of CNS infection. They typically occur in infants and children ages 6 months to 5 years. It is thought that the rapid rise or defervescence of a fever is the at-risk period, rather than the absolute height of the fever. Many parents worry about the subsequent risk of epilepsy after a febrile seizure, although studies have born out that the risk is only slightly increased. The risk of epilepsy in the general population is thought to be 0.5 to 1% while the risk in a patient who has had a febrile seizure is 1 to 2%. Although generally benign in course, febrile seizures can sometimes be the presenting complaint of infants and children with CNS infection such as meningitis. Febrile seizures are classified as either simple or complex. Simple febrile seizures are brief (<15 minutes), single, and nonfocal or generalized tonic-clonic. Complex febrile seizures are prolonged, recurrent (more than one within 24 hours), or typically focal.

Differentiating a benign febrile seizure from one that heralds CNS infection can be difficult. The AAP has published consensus guidelines for the evaluation and management of febrile seizures.59 Laboratory and radiographic evaluation should be directed at finding the source of the fever, not driven by the seizure itself. The AAP suggests that a lumbar puncture be “strongly considered” after the first febrile seizure in infants younger than 12 months of age, in children who have received prior antibiotic therapy due to concern about missing CNS infection or in those who demonstrate symptoms or signs worrisome for meningitis. Routine referral for neuroimaging or electroencephalography is not indicated.60 There is also no role for antiepileptic therapy after a single febrile seizure.

Parents should be warned that 33% of children who have a febrile seizure will have another one and that 75% of these will occur within a year. The younger a child is at the age of the first seizure, the more likely it is that a second one will occur. Children who seize at lower temperatures are also at higher risk for recurrence (35% at 38.5°C vs. 13% at 40°C).

Fever and Petechiae

The presence of a petechial rash in the setting of a febrile illness is classically associated with meningococcal infection. In fact, Baker and colleagues found that the incidence of meningococcal infection was 7 to 11% in patients hospitalized with fever and petechiae.61 The rate of bacteremia of any cause was found to be much lower (1.9%) in an ED population. The differential diagnosis of fever and petechiae also includes disseminated intravascular coagulation, Rocky Mountain spotted fever, pneumococcal bacteremia, Streptococcus pyogenes infection, various viral infections, idiopathic thrombocytopenic purpura, Henoch-Schonlein purpura, and leukemia. Petechiae can also be caused mechanically from tourniquetting, wretching, or violent coughing. Petechiae due to vomiting or coughing is typically confined to the skin above the nipple line, but petechiae caused by serious bacterial illness can have any distribution.

Because of the risk of serious illness in children with fever and petechiae, blood should be obtained for CBC and blood culture. In cases associated with pharyngitis, testing for group A Streptococcus infection is indicated. Mandl and colleagues performed a prospective cohort study of 411 patients presenting to a pediatric ED with fever greater than 38.0°C and petechiae with the hopes of identifying clinical and laboratory criteria that would provide a means to screen for bacteremia.62 They found that an abnormal WBC count (<5,000 WBCs/mm3 and >15,000 WBCs/mm3) or abnormal coagulation studies were predictive but not diagnostic of invasive bacteremia. Also, well-appearing children with normal WBC and coagulation studies were exceedingly unlikely to have invasive bacteremia. In their study, only two well-appearing children had bacteremia (S. pneumoniae), and this study was done in the pre-Prevnar era. Empirical antibiotic therapy (ceftriaxone, 50 mg/kg IV/IM) should be considered in all children presenting with fever and petechiae, even if an outpatient disposition is anticipated.

Kawasaki Disease (Mucocutaneous Lymph Node Syndrome)

Kawasaki disease is one of the most common vasculitides in childhood and should be considered in any infant or child with prolonged fever.63 A more complete discussion on KD can be found in Chapter 169. Accurate diagnosis is important because the main complication of KD is the development of coronary artery aneurysms. Some patients will present with “incomplete KD,” which occurs when not all diagnostic criteria are met. Despite the lack of classic findings, these children are still at risk for coronary complications. Laboratory abnormalities found in cases of KD include leukocytosis, thrombocytosis (platelet counts as high as 1,000,000/mm3), and evidence of systemic inflammation with elevation in the erythrocyte sedimentation rate and C-reactive protein.

Children with suspected KD should be hospitalized and therapy with intravenous immune globulin (2 g/kg infused over 10–12 hours) and aspirin (initial dose 80–100 mg/kg daily divided every 6 hours).64 Pediatric cardiology consultation for echocardiography is also indicated.

Toxic Shock Syndrome

Toxic shock syndrome refers to the toxin-mediated clinical syndrome that occurs with infection with S. aureus, although a similar illness is caused by infection with group A Streptococcus. The toxin implicated in TSS is an exotoxin termed TSS toxin 1. The syndrome is classically associated with tampon use by menstruating women, although cases also occur in males and prepubertal girls and also result from other sources of infection with S. aureus.65–67

Clinical manifestations of TSS include fever (>38.9°C), hypotension, diffuse erythroderma, as well as multisystem involvement. Patients may present with vomiting or diarrhea, severe myalgias, oropharyngeal hyperemia, or altered mental status. Laboratory abnormalities are common and include elevated creatine phosphokinase, elevated blood urea nitrogen or creatinine, transaminitis, and thrombocytopenia. The Centers for Disease Control and Prevention has developed a set of findings for case definition (Table 165-3).

Treatment of TSS involves aggressive fluid resuscitation as these patients typically have immense requirements and antibiotic therapy with clindamycin (25–40 mg/kg per day in three divided doses) as well as vancomycin (40 mg/kg per day IV in four divided doses).
**Fever and Underlying Chronic Medical Illness**

**Oncology Patients**

Children with cancer, particularly those undergoing treatment with cytotoxic chemotherapy, are at particular risk for sepsis and bacterial infection. These life-threatening infections are most common during periods of profound neutropenia. Neutropenia is defined as an absolute neutrophil count of less than 500/mL or an absolute neutrophil count of less than 1000/mL and falling. Children with cancer also frequently have indwelling catheters, predisposing them to surgical line infections.

Causative organisms include both gram-positive and gram-negative bacteria. Staphylococci and streptococci as well as *Pseudomonas* are frequent pathogens. Often, patients with focal infection may not present with classic signs due to their leukopenia. Focal infections specific to cancer patients include mucosal infections, focal infections of the terminal ileum and cecum.

Children presenting with fever and possible neutropenia require prompt evaluation. Blood should be obtained for a CBC and manual differential as well as culture. If a central line infection is suspected, a separate culture from the line should be obtained. Once appropriate laboratory studies are obtained, empirical antibiotic therapy should be initiated without waiting for the laboratory results. Appropriate monotherapy antibiotic regimens include cefepime, 50 mg/kg IV every 8 hours, or ceftriaxone, 50 mg/kg IV every 8 hours. Vancomycin, 40 to 60 mg/kg every 6 to 8 hours, should be added for antistaphylococcal coverage in children with suspected central line infections or skin and soft tissue infections. Children with fever and neutropenia are rarely if ever treated as outpatients; if so, ceftriaxone, 50 mg/kg IV every 24 hours, is given and close follow-up is essential.

**Acquired Immunodeficiency Patients**

Children with the acquired immunodeficiency syndrome (AIDS) are at risk for bacterial infection due to a whole host of different organisms, some common, some uncommon. Infections specific to AIDS include cryptococcosis, infection with *Mycobacterium tuberculosis*, *Mycobacterium avium*–*intracellulare*, and *Pneumocystis jiroveci* (carinii). Viral infections such as cytomegalovirus and Epstein-Barr virus are also common.

Laboratory evaluation should be directed by the history and physical examination, and early initiation of broad-spectrum antibiotic therapy is recommended.

**Sickle Cell Disease**

Febrile children with sickle cell disease are at particular risk for overwhelming infection. In fact, infection is the most common cause of sickle cell–related death, occurring in up to 40% of patients. Recurrent episodes of splenic infarction lead to functional asplenia early on in life. Thus, these patients are at particular risk for infection with encapsulated organisms including *S. pneumoniae* and *H. influenzae*. Because of this risk of bacterial disease, it is recommended that all children with sickle cell disease should be completely immunized. Prophylaxis with penicillin is recommended in children under the age of 5 years, after which it can be safely discontinued in children who have not had a prior severe pneumococcal infection or surgical splenectomy. The dose of penicillin is 125 mg orally (PO) twice daily until 3 years of age (at about 14 kg) and 250 mg PO twice daily after 3 years of age. High-risk criteria for bacterial infection include toxic appearance, temperature greater than 40°C, an abnormal WBC count (<5,000 or >30,000 WBCs/mm³) and noncompliance with penicillin prophylaxis. Sickle cell patients are at particular risk for *Salmonella* osteomyelitis. All patients presenting with fever and sickle cell disease should have a CBC, reticulocyte count, and blood culture drawn. A reticulocyte count is important as many infections (e.g., parvovirus B19) can induce life-threatening aplastic crisis. It is important to remember that infection also predisposes children with sickle cell disease to acute chest syndrome. Common causes of infection include *Chlamydia pneumoniae*, *Mycoplasma*, RSV, *S. aureus*, and *S. pneumoniae*. Further laboratory and radiographic evaluation should be directed based on the presenting history and physical.

High-risk patients should be admitted for further evaluation and antibiotic therapy. Low-risk patients may be treated with a single dose of intravenous/intramuscular antibiotics, typically ceftriaxone, 50 mg/kg, and discharged to close outpatient follow-up. All patients should be reevaluated within 24 hours or sooner if the clinical condition deteriorates.

Osteomyelitis typically presents with fever and bone pain. As patients with sickle cell disease may have frequent bone pain due to vaso-occlusive crisis, the diagnosis often can be difficult. All patients should have a CBC with differential, erythrocyte sedimentation rate, and blood culture drawn, and a radionuclide bone scan may help to localize the infection. If *Salmonella* infection is suspected, a stool sample should be sent for culture.

**Congenital Heart Disease**

Children with congenital heart disease are at high risk for cardiovascular complications in the setting of febrile illness. Often, relatively minor viral illness can produce significant...
pharyngeal (VP) shunts are at risk for shunt infection. If shunt infection is suspected, neurosurgical consultation should be obtained and a sample of CSF obtained. This is typically accomplished by sterile aspiration of fluid from the shunt reservoir. *S. aureus* and *S. epidermis* are the usual causative organisms. Because altered mental status may also accompany shunt infection, a computed tomography scan should be obtained to assess ventricular size. Children with suspected shunt infection are typically managed as inpatients and antibiotics should begin as soon as possible.

### KEY CONCEPTS

- Fever is the most common complaint among pediatric patients presenting to the ED, although rates of bacterial illness are lower since the advent of universal vaccination for HIB and *S. pneumoniae*.
- Infants less than 3 months of age are at higher risk for bacterial illness with fever due to their immature immune systems and incomplete vaccination status, making aggressive workup of these children important.
- The most common cause of serious bacterial illness in children continues to be UTIs, and the only reliable method to obtain urine in a non-toilet-trained infant is through bladder catheterization or suprapubic aspiration.
- RSV is a common viral cause for fever and respiratory distress in infants, although the presence of RSV does not lower the risk of concomitant serious bacterial illness in children less than 28 days of age.
- Children presenting with fever and petechiae are at risk for infection with meningococcus; blood should be obtained for CBC and culture, and most children should be treated with empirical parenteral antibiotics.

Respiratory distress from upper airway obstruction is an unusual but potentially catastrophic emergency in young children. It may be caused by a number of different processes, alone or in combination, including an acute infectious process, a congenital anomaly, or a foreign body in the airway or esophagus. A working knowledge of the anomalies and diseases of the upper airway is of primary importance in pediatric emergency medicine. Classification of airway pathology can be based on the anatomic location, the patient’s age, the urgency of the symptoms, and whether it is a congenital or acquired lesion or an infectious or noninfectious process. The starting point for any classification is an appreciation of the unique aspects of pediatric airway anatomy.

A number of differences between the adult and pediatric airway are important in airway management (Fig. 166-1). An infant’s tongue is disproportionately large in relation to the mouth and protrudes back into the posterior of the pharynx. The tongue is a formidable obstacle when performing bag-mask ventilation and visualizing the airway. In the setting of hypotonia, posterior displacement of the tongue is the most common cause of functional upper airway obstruction. The infant larynx is more anterior and caudad, or higher in the neck relative to the cervical spine (at C3-4), than in an adult (at C4-5). The anterior aspect of the vocal cords is tipped inferiorly. The narrowest site of the infant airway is at the cricoid ring rather than the cords as in an adult. A child’s epiglottis is relatively larger, longer, and omega shaped. It extends vertically beyond the opening of the cords, thus making a complete view of the airway difficult. The caliber of all airway structures is small; newborn tracheal length is 57 mm and laryngeal diameter is 4 mm. All cartilaginous supporting structures are soft, pliable, and prone to collapse. Finally, a prominent occiput allows passive flexion of the head and neck on the cervical spine. In aggregate, these anatomic features of the pediatric airway predispose infants and young children to functional upper airway obstruction and make airway intervention technically challenging.

The type and size of equipment required for management of the pediatric airway are derived from the anatomy just discussed. A face mask should be sized so that the top and bottom rims fit on the bridge of the nose (below the eye) and in the cleft of the chin. A straight (Miller) blade is generally used for endotracheal intubation in infants and young children because the tip of the straight blade lifts the epiglottis up and out of the line of vision of the airway. Endotracheal tube size is a function of the patient’s size. For children older than 1 year, endotracheal tube size (internal diameter in millimeters) can be estimated by the formula (age in years/4) + 4; for uncuffed tubes, one should use one half size smaller except for 3.0-mm tubes. Alternatively, endotracheal tube size can be estimated by using a length-based measuring system such as the Broselow tape. Recent evidence suggests that cuffed endotracheal tubes may be used safely in children of all ages. Cuffed endotracheal tubes allow for the delivery of high pressures during ventilation without the air leak associated with uncuffed tubes and without increased complications such as subglottic stenosis.1,2

The spectrum of clinical findings in children who arrive at the emergency department with symptoms related to upper airway pathology is broad and includes the following general categories:

- **Acute infections of the upper airway range in severity of presentation from the child with mild distress and self-limited signs and symptoms, to the child with abrupt onset of rapidly progressive airway obstruction.**
- **Undiagnosed congenital anomalies of the airway and surrounding structures may be manifested as chronic or progressive stridor or difficulty feeding.** An infant with a congenital airway anomaly in whom an acute airway infection develops is at higher risk for decompensation and respiratory failure.
- **Upper airway obstruction from a foreign body in the airway or esophagus can cause partial or complete airway obstruction and may require advanced airway management skills.**

**STRIDOR**

Stridor is the classic sound associated with upper airway obstruction.3,4 It is derived from the Latin stridulus, meaning harsh or grating. Stridor is caused by partial airway obstruction and the resultant turbulent airflow through a portion of the airway from the nose to the trachea. It is not a diagnosis in itself but an important sign that must be thoroughly investigated. Stridor should be timed in the respiratory cycle (inspiratory, expiratory, biphasic) and assessed in terms of quality (coarse, high pitched).
The airway can be artificially divided into four regions: the nose and pharynx, the supraglottic structures, the glottis and immediate subglottic area, and the intrathoracic trachea (Fig. 166-2). Stridor has different characteristics, depending on its exact origin in the airway (Table 166-1).

Stridor from the nose and pharynx has a sonorous, gurgling, and coarse quality. The voice may have a muffled or “hot potato” quality. An example of when this occurs is in the presence of a peritonsillar abscess. High-pitched, inspiratory stridor comes from the supraglottic and immediate subglottic trachea. Inspiratory stridor is heard with pathology in this region because the extrathoracic airway narrows with inspiration as a result of atmospheric pressure outside the airway being slightly higher than that inside the airway. The voice may sound hoarse or weak. Examples include viral croup and laryngomalacia.

Biphasic stridor is heard with inspiration and expiration and usually suggests a fixed lesion that does not change in size at the glottis or cricoid ring with respiration. Examples of conditions resulting in biphasic stridor are a laryngeal web and vocal cord paralysis. Stridor from the lower part of the trachea is usually expiratory. Bacterial tracheitis and a foreign body are examples.

OVERVIEW OF THE EVALUATION AND MANAGEMENT OF A CHILD WITH AN UPPER AIRWAY OBSTRUCTION

Evaluation of a child with signs of airway obstruction begins with careful observation of the child at rest (work of breathing, respiratory rate, alertness, color) and during activity (crying, feeding). In most cases, observation and a carefully obtained history will provide most clues to the correct diagnosis. Important items to be elucidated in the history include the following:

- Onset and duration (acute, chronic)
- Associated symptoms (respiratory distress, fever, toxicity, drooling, cyanosis)
- Progression with age (number of bouts/severity of “croup” with increasing age)
- Exacerbations (supine vs. prone position, upper respiratory infection [URI], crying)
- Feeding pattern (dysphagia, feeding abnormalities)
- Airway procedures (intubation in the neonatal period)
- Choking episode (foreign body aspiration)
- Baseline noises, quality of cry and voice (location of obstructive lesion)

The initial physical examination includes assessment of the severity of respiratory distress (respiratory rate, retractions, flaring, heart rate) and the presence of respiratory failure (extreme distress, hypoventilation, altered mental status, dusky skin color, cyanosis, hypotonia). The character and timing of stridor, as well as the symmetry and quality of breath sounds, are important observations.

Definitive airway management always takes precedence over laboratory and radiographic tests in a patient with an acute airway emergency. In a stable patient with an uncertain diagnosis, an individualized diagnostic evaluation is important.

In the stable patient, radiographs of the soft tissues of the neck may be helpful and should include both lateral and anteroposterior views. These views are helpful to assess adenoid and tonsillar size, the contour of the epiglottis, the thickness of the retropharyngeal soft tissue space, the vallecula, the aryepiglottic folds, and the tracheal air column (Fig. 166-3).

Optimally, the child’s head should be positioned in extension and the film taken during inspiration. Views of the chest may be helpful to assess heart size, location of the aortic arch, pulmonary pathology, and the trachea and bronchi.

Additional studies may be indicated in specific settings. Bedside fiberoptic nasopharyngoscopy can be performed without anesthesia, allows visualization and movement of supraglottic structures and vocal cords, and may permit fiberoptic-assisted intubation via the nasopharyngoscope. An esophagogram may help define lesions compressing the airway and trachea. Computed tomography (CT), magnetic resonance imaging (MRI), and fiberoptic and rigid bronchoscopy should be considered on an individual basis.
SPECIFIC DISORDERS

Supraglottic Airway Diseases

Perspective

The supraglottic portion of the airway includes the nose, pharynx, epiglottis, and surrounding structures. Pathology of the nose and pharynx is commonly associated with noisy, congested breathing and respiratory distress. Congenital lesions involving these structures may cause mild symptoms at baseline but dramatic distress when the patient is stressed with a superimposed infectious process. Among the congenital lesions with which the emergency physician should be familiar are choanal atresia, macroglossia, micrognathia, thyroglossal duct cyst, and lingual thyroid. Important acquired causes include nasal foreign body, nasal polyps, hypertrophic tonsils and adenoids, epiglottitis, retropharyngeal abscess, peritonsillar abscess, pharyngitis, mononucleosis, and upper airway foreign body. The most common ones are discussed in the following sections.

Congenital Lesions

Choanal atresia, the most common congenital anomaly of the nose, is caused by persistence of the bucconasal membrane or a bony septum in the posterior nasum. Infants are “preferential nose breathers” because they breathe through their nose when their mouth is closed at rest and in order to suck and swallow. This breathing preference is a result of the posterior aspect of the soft palate extending downward and contacting the tip of the epiglottis. Bilateral choanal atresia is a life-threatening emergency that is identified shortly after birth. Infants with bilateral choanal atresia become acutely distressed and cyanotic at birth and are managed with an oral airway that opens the mouth to allow a passage for breathing. Surgical correction of the obstructing membrane is required. Unilateral choanal atresia may go undetected in the nursery and become apparent only when the normal, patent nares are obstructed by swelling or secretions, most frequently from a URI.

Macroglossia is associated with a number of conditions, including Down syndrome, glycogen storage disease, and congenital hypothyroidism. The tongue is abnormally large and protrudes posteriorly into the hypopharynx. The increased secretions and swelling associated with a URI exacerbate the underlying obstruction, and stridor or labored breath sounds are produced.

Micrognathia is associated with syndromes such as Pierre Robin and Treacher Collins. A small mandible posteriorly displaces the normally sized tongue. Signs of obstruction often worsen when the patient is supine.

Retropharyngeal Abscess

Perspective. A retropharyngeal abscess is a potentially life-threatening airway emergency resulting from infection of the retropharyngeal soft tissue space. The retropharyngeal space is a potential space between the posterior pharyngeal wall and the prevertebral fascia that extends from the base of the skull to the level of T2. It is rich in lymph tissue that drains the nose, pharynx, sinuses, and ears. An abscess may result from direct trauma, suppuration of lymph nodes, or hematogenous spread. Most cases are seen in children younger than 3 years. These infections are commonly polymicrobial, with Streptococcus and anaerobes the most commonly isolated organisms. Several recent case reports highlight the emerging role of methicillin-resistant Staphylococcus aureus in these infections.

Clinical Features. The variable manifestations of a retropharyngeal abscess often make it a challenging diagnosis in younger children. Common signs and symptoms include fever, sore throat, neck stiffness/nuchal rigidity, torticollis, trismus, neck swelling, drooling, stridor, and a muffled voice. In a prospective study of 17 patients with retropharyngeal abscess, stridor and airway obstruction were observed in half (56%) of the patients. This common finding of acute airway obstruction in children is a function of the high position of the larynx in the neck. Such anatomy places the airway proximate to and easily compressed by the bulging retropharyngeal mass. In patients with airway compression, the clinical appearance may resemble epiglottitis. With less obvious signs of airway obstruction, patients can exhibit a mixture of symptoms (fever, neck stiffness, generalized toxicity) suggesting meningitis or sepsis. Complications of a retropharyngeal abscess can be serious: generalized sepsis, aspiration pneumonia, mediastinitis, and empyema.

Diagnostic Strategies. Careful evaluation of airway patency takes precedence in managing a child with a presumed retropharyngeal abscess. Examination of the pharynx may reveal bulging of the posterior pharyngeal wall. A soft tissue lateral view of the neck may be helpful to establish the diagnosis; in the normal patient the width of the retropharyngeal space should not exceed the diameter of the adjacent vertebral body (Fig. 166-4). An air-fluid level is more commonly seen with perforations and anaerobic infections. Redundant soft tissue of the retropharyngeal space complicates interpretation of lateral neck films in young infants with a retropharyngeal abscess. Artifactual widening of a normal retropharyngeal space is commonly seen when the radiograph is taken with the head and neck in flexion or during exhalation (or both). CT may be beneficial in selected cases.

Management. The size of the abscess, the degree of airway obstruction, and the overall toxicity of the patient dictate management. The need for intubation or surgical drainage is determined on an individual basis, and these patients generally benefit from involvement of an ear, nose, and throat specialist.

Figure 166-4. Retropharyngeal abscess. Note the widened retropharyngeal soft tissue space.
Epiglottitis

**Perspective.** Although still among the most feared pediatric emergencies, the incidence of acute epiglottitis has declined markedly since widespread administration of *Haemophilus influenzae* type b vaccine. First licensed in 1985 for children 24 months old, the vaccine became available for immunization of infants 2 months of age in 1990. A study that compared epiglottitis before and after 1990 revealed a drop in the annual incidence of epiglottitis from 10.9 to 1.8 per 10,000 admissions.

**Principles of Disease.** Epiglottitis is an invasive bacterial disease that causes inflammation and edema of the epiglottis, aryepiglottic folds, and surrounding supraglottic tissues. As these structures become inflamed and distended, they protrude downward and over the glottic opening. Historically it was caused by *H. influenzae* type b in children 3 to 7 years of age and occurred year-round. This traditional profile has changed. In a survey of patients with epiglottitis since 1990, the average patient is older (80 vs. 35 months) with varying microbiology. *H. influenzae* type b is seen in a small minority of patients, and organisms such as group A beta-hemolytic *Streptococcus*, *S. aureus*, and *Streptococcus pneumoniae* are more common. Noninfectious causes are rare and include thermal injury from swallowing hot liquids.

**Clinical Features.** Epiglottitis is classically acute in onset. It is marked by high fever, intense sore throat, toxicity, and rapid progression. In one study, 85% of children with epiglottitis were symptomatic for less than 24 hours. Children with epiglottitis appear anxious and maintain themselves in a “sniffing” or “tripod” position with the jaw jutting forward and the neck extended to maximize airway patency. As symptoms worsen, cough and phonation are usually absent. Drooling is prominent because of an inability to swallow. A study of children 2 to 18 years of age revealed that fever, difficulty breathing, irritability, change in voice or cry, stridor, and retractions were common initial symptoms that occurred in more than 80% of patients. Singer and colleagues showed that in children younger than 24 months, toxicity, altered mental status, dyspnea, stridor, retractions, and fever were common initial symptoms. Losek and coworkers in a study of 236 patients reported that 7 patients (3%) died. The correct diagnosis of epiglottitis was not made in 11 of 58 (19%) children younger than 2 years and in 49 of 178 (28%) children between 2 and 18 years old. In the older patient (e.g., in adolescents), severe odynophagia or dysphagia in the absence of signs of pharyngeal swelling, erythema, or exudates should raise suspicion for this diagnosis. The older patient is less likely to show dramatic signs of upper airway obstruction as compared with the younger child, because the diameter of the airway is relatively larger and thus takes a greater degree of swelling to produce symptoms. Incorrect diagnoses in patients who died included croup, summer virus, and pharyngitis. Group was the most commonly assigned misdiagnosis and more often made in the setting of very young children or those in whom drooling or difficulty swallowing were not prominent. A majority of patients with *H. influenzae* epiglottitis have bacteremia (50–75%).

**Diagnostic Strategies.** Direct examination or manipulation of the pharynx should be avoided in cases in which epiglottitis is strongly suspected. Stimulation of the posterior of the pharynx with subsequent contraction of the pharyngeal muscles may increase airway obstruction. In adult patients this is less commonly a concern because of the relatively larger upper airway. A lateral neck radiograph can be helpful to confirm the diagnosis and should be evaluated for an enlarged epiglottis (“thumbprint sign”; Fig. 166-5), thickened aryepiglottic folds, lack of air in the vallecula, and a dilated hypopharynx. Careful observation of a child with suspected epiglottitis is essential. Laboratory tests, intravenous fluids and antibiotics, blood and epiglottis cultures, and sedation are all important considerations once the airway has been secured.

**Management.** The clinical features of classic epiglottitis are usually sufficiently characteristic that diagnostic tests are not necessary and should be avoided. The importance of securing the airway takes precedence over diagnostic evaluation. A “stable” patient who is maintaining a patent airway and adequate oxygenation should not be moved or repositioned for examination, laboratory tests, or radiography. Such patients should be carefully transported to a setting where definitive airway management can be achieved in a controlled fashion. If diagnostic studies are needed, constant and close observation is vital.

Careful decision-making is essential when a child with epiglottitis, or suspected epiglottitis, requires transport. A survey of pediatric intensive care and emergency physicians reported that half recommended intubation before interhospital transport in all cases. The remainder individualized the recommendation for pretransport intubation based in part on the referring physician’s perceived ability to intubate the child. Successful observation without intubation during transport has been reported. However, this observation occurred in the selective setting of a pediatric intensive care unit (ICU) where several physicians with advanced training in anesthesia and pediatric critical care were on site at all times. Clearly, this is not the environment of most emergency departments and critical care units, and expeditious controlled intubation remains optimal management.

Unstable patients with respiratory failure require assisted ventilation. Bag-valve-mask ventilation should be attempted first and, if successful, continued until intubation can be performed by the emergency physician or anesthesiologist. If neither bag-valve-mask ventilation nor intubation is successful, more aggressive techniques such as needle cricothyroidotomy or tracheostomy may be indicated. Regardless of the approach to securing the airway, it is prudent for the emergency physician to as rapidly as possible consult other experts in airway management such as anesthesia (fiberoptic
intubation) and head and neck or general surgery (surgical approaches) so that a plan of approach can be made and morbidity reduced.

**Diseases of the Larynx**

The larynx and vocal cords occupy an important region in the airway that is often associated with airway pathology causing obstruction. Many of these obstructing conditions are congenital lesions, including laryngomalacia, a laryngeal web, and vocal cord paralysis. Acquired lesions include laryngeal papillomas.

**Congenital Lesions**

*Laryngomalacia*, the most common cause of chronic stridor in infants, is a result of incomplete development of the supporting cartilage of the larynx. With inspiration, the long, floppy epiglottis, arytenoids, and aryepiglottic folds are drawn into the larynx and create a partial obstruction (Fig. 166-6). Baseline inspiratory stridor begins shortly after birth and worsens with supine positioning and increased respiratory effort (crying, URI). Laryngomalacia is rarely associated with significant respiratory distress, feeding difficulties, or failure to thrive. Most patients experience complete resolution of symptoms by 2 years of age. Fiberoptic bronchoscopy has been used to confirm the diagnosis and exclude coexisting anomalies such as vocal cord paralysis and subglottic stenosis, which are found in approximately 20% of patients.

*Vocal cord paralysis* is the second most common cause of chronic stridor in infants. Bilateral vocal cord paralysis results in severe respiratory distress and stridor and is usually associated with serious central nervous system abnormalities such as Arnold-Chiari malformation. Unilateral vocal cord paralysis is most commonly left-sided and related to traction on the left recurrent laryngeal nerve at birth or compression from mediastinal structures. Infants with unilateral vocal cord paralysis have a hoarse, weak cry. Stridor often worsens with distress and improves with positioning of the affected side down.

A *laryngeal web* results from failure of complete canalization of the airway. Most webs lie between the cords and appear as a partial anterior fusion (Fig. 166-7). The spectrum of symptoms reflects the size of the web. Small webs may cause a hoarse, weak cry and mild stridor. Larger, more complete webs are associated with aphonia and severe distress.

**Laryngeal Papillomas**

Laryngeal papillomas arise from the laryngeal epithelium and may result from perinatal or postnatal exposure to human papillomavirus. When acquired in the prenatal period, hoarseness, abnormal cry, and inspiratory stridor commonly occur by 3 to 4 years of age. Symptoms can progress to severe respiratory distress as the lesions enlarge and obstruct the larynx.

**Subglottic Tracheal Diseases**

The subglottic trachea is the origin of the high-pitched inspiratory sound commonly associated with upper airway obstruction. The subglottic space is the narrowest part of the airway in children younger than 8 years and is completely surrounded by the cricoid ring. Such anatomy predisposes this part of the airway to obstruction. Subglottic narrowing or stenosis can result from a congenital anomaly, inflammation from infection, and trauma associated with prolonged intubation.
PART VII
Special Populations / SECTION ONE • The Pediatric Patient

Congenital Lesions

Congenital laryngotracheal (“subglottic”) stenosis is a result of a congenital defect in canalization of the subglottic trachea. Deformity of the cricoid ring is usually seen. Infants with severe stenosis have stridor at birth. Mild lesions may be asymptomatic until additional obstruction from infection or inflammation occurs. Subglottic stenosis is also an acquired condition that occurs after prolonged intubation or blunt trauma to the neck.

A subglottic hemangioma is a less common cause of stridor and subglottic airway obstruction in infants. The infant is usually asymptomatic at birth, but stridor (which may be biphasic) and cough develop within the first few weeks to months of life. Symptoms generally peak at 6 months as a result of rapid growth of the infant and the hemangioma during the first months of life. Respiratory symptoms worsen with crying and agitation. Cutaneous hemangiomas are seen in approximately half of cases. Hemangiomas of the airway may be seen on plain film as an asymmetrical lesion along the tracheal air column.

Viral Croup

Principles of Disease. Croup (laryngotracheobronchitis) is the most common cause of upper airway distress and obstruction in childhood. It occurs most commonly in late fall, early winter, and spring, with a peak incidence at 2 years (range, 6 months to 6 years) of age. Rarely, viral croup is seen in older, healthy children.

Parainfluenza virus type 1 accounts for about half of cases, with parainfluenza virus types 2 and 3, respiratory syncytial virus, influenza A and B virus, and rhinovirus responsible for the remainder.38 Croup is caused by inflammation, exudate, and edema of the loosely adherent mucosal and submucosal tissues of the subglottic space. The inflamed mucosa expands into the airway lumen because the cricoid forms a complete cartilaginous (nonexpanding) ring in this part of the trachea.

The true incidence of croup is uncertain. Most children with croup have an uncomplicated course, and many cases are managed without medical intervention. Only a small percentage of those who receive urgent care require hospitalization. Croup is recurrent in a small number of patients. A subset of children with croup have involvement of the lower airway and exhibit bronchoconstriction, lower airway edema, and atelectasis.

Clinical Features. Croup can generally be diagnosed clinically. Children with typical croup have a constellation of symptoms, including a barky cough, hoarse voice, and high-pitched, inspiratory stridor. These findings usually follow a prodrome of mild fever and URI symptoms lasting several days.

Scoring systems have been developed for assessment of croup and include an evaluation of worsening stridor, retractions, cyanosis, heart rate, and respiratory rate. Although a formal croup score is often not assigned in many clinical settings, the determination of mild, moderate, or severe croup should be based on careful evaluation of these five signs, as well as mental status and air movement. Mild croup is characterized by an intermittent barky cough, stridor with agitation but not at rest, mild tachypnea, and tachycardia. A child with mild croup is minimally distressed and well hydrated and has normal mental status. Moderate croup is characterized by audible stridor at rest, worsening stridor with agitation, a barky cough, and increased work of breathing (retractions, tachypnea, tachycardia). A patient with moderate croup may be fussy but is alert, interactive, and comforted by parents. Hypoxia is atypical in mild or moderate croup. When seen, it may signify concomitant lower respiratory disease, another disease process, or severe croup.

Laboratory tests are nondiagnostic. Radiographic studies of the neck are useful when the diagnosis is in doubt, but they do not change management. The classic finding in croup is a tapered narrowing of the normal shouldered appearance of the subglottic trachea such that it has the appearance of a pencil or steeple.

Management. Glucocorticoids are the mainstay of treatment of croup, resulting in reduced symptoms, need for aerosolized epinephrine, readmission to the emergency department, and shorter hospital stays.39-44 Evidence for the use of routine steroids in croup was Geelhoed and Macdonald’s comparison of the experience at Princess Margaret Hospital for Children before and after steroids became mandatory in the treatment of croup in patients in the ICU.45 Before 1989, less than 5% of ICU patients received steroids. At that time, an average of 11% were intubated yearly, and the total ICU days were 129 (yearly average). Beginning in 1989, every child admitted to the ICU received 0.6 mg/kg dexamethasone intramuscularly. The intubation rate declined to 1% (yearly average), and total ICU days dropped to 21 (yearly average).

The role of oral, parenteral, and inhaled steroids in the treatment of croup has been debated for decades.39 A meta-analysis of nine studies investigating steroid use in hospitalized patients with moderate croup suggested that (1) steroid therapy resulted in faster improvement in hospitalized patients, (2) steroids decreased the incidence of intubation, and (3) higher doses (>0.3 mg/kg dexamethasone) were more effective than lower doses.40 Subsequent to this study, Geelhoed and Macdonald demonstrated that oral dexamethasone in doses as small as 0.15 mg/kg was as effective as higher doses in decreasing the duration of symptoms and hospitalization time.41 Steroids in patients with mild croup have also been shown to improve symptoms and reduce the need for return to medical care.44

Budesonide is an inhaled steroid with potent topical anti-inflammatory properties. A single dose (2 mg) of nebulized budesonide was shown to shorten emergency department stay, decrease the rate of hospitalization, and cause a more rapid improvement in symptoms in children with mild to moderate croup evaluated in the emergency department.41 Inhaled budesonide (2 mg per dose) was shown to be as effective as oral dexamethasone (0.6 mg/kg) in decreasing the duration of hospital stay, improving clinical symptoms, and decreasing the ongoing requirement for aerosolized epinephrine. Johnson and colleagues found intramuscular dexamethasone to be superior to nebulized budesonide in reducing rate of hospitalization,42 while other studies have found the two treatments comparable.43

Aerosolized epinephrine, either racemic epinephrine (containing d and l isomers) or l-epinephrine, act on alpha-adrenergic receptors in the subglottic mucosa.46 Through vasoconstriction, epinephrine reverses edema and relieves acute symptoms in a subset of patients. It is a temporizing measure with a quick onset of action (within 10 minutes) and duration of effect between 1 and 2 hours. Racemic epinephrine has traditionally been preferred over l-epinephrine because the racemic mixture has been associated with fewer cardiovascular side effects. However, the l form of epinephrine is the active isomer and has the same degree of safety and efficacy as racemic epinephrine47; either form may be used. The “rebound” phenomenon of epinephrine is defined as recurrence or worsening of the patient’s pretreatment symptoms when aerosolized epinephrine wears off. This rebound is rarely clinically significant if steroids are given early in management.48 Many patients with moderate croup benefit from aerosolized epinephrine. It has been demonstrated that a subset of these patients can be safely discharged from the emergency department after a post-treatment observation
period of 2 to 4 hours. A retrospective study evaluating the policy of discharging selected patients after treatment with racemic epinephrine yielded favorable results. Of 50 patients discharged after the administration of epinephrine, none were subsequently hospitalized and only 1 required retreatment within 48 hours as an outpatient. Importantly, 92% were discharged on a regimen of steroids. The investigators recommend that children with moderate croup who have received aerosolized epinephrine can be safely discharged (1) after 2 hours of observation after administration of epinephrine, (2) if they are free of stridor and retractions, and (3) if they have access to follow-up care. They also recommend administration of steroids in these patients. The decision to discharge after administration of epinephrine should also be based on the patient’s symptoms such as dehydration, preexisting airway pathology, and other congenital anomalies.

Cool mist has long been advocated as a useful therapy but has not been demonstrated to improve outcomes. It is hypothesized to act by moistening thickened secretions, thereby making them easier to mobilize out of the airway. A randomized trial of mist therapy in moderate croup showed no clear benefit in improving oxygen saturation, respiratory rate, or assessment times.

A small percentage of patients with croup require admission. The decision to admit a child with moderate croup is based on a number of factors: the severity of symptoms at initial evaluation, persistence of respiratory distress, stridor at rest, oxygenation, response to treatment (humidification and aerosolized epinephrine), hydration, history suggesting airway pathology or recurrent croup, young age (<6 months), high fever, overall toxicity, and parental reliability (Box 166-1).

Severe croup is rare and associated with signs of impending airway obstruction and respiratory failure: fatigue, hypoxia, hypercapnia, abnormal mental status, extreme respiratory distress, and stridor. Since the advent of steroid administration, only an estimated 1 to 2% of patients with croup require intubation. Ideally, intubation should be performed under controlled circumstances. Orotracheal intubation with an endotracheal tube at least a half size smaller than expected for the child’s size is often necessary. If the tube that can be passed is too small to allow adequate ventilation, tracheostomy may be required. The decision to extubate a child with severe croup is complex; age, coexisting congenital lesions, and length of intubation are all variables that should be considered.

**Spasmodic Croup**

Spasmodic croup is a somewhat indistinct clinical entity in which many of its features overlap those of viral croup. It is characterized by the sudden onset of severe stridor and a barking cough without a viral prodrome. It may be recurrent and has been associated with allergy and gastroesophageal reflux. Previous parainfluenza infection has been postulated as a predisposing condition for a hypersensitivity reaction on later exposure to the virus. There is little in the literature to delineate the difference between spasmodic and viral croup.

**Diseases of the Trachea**

Obstruction of the trachea distal to the subglottic space can be a result of both congenital and acquired lesions.

**Congenital Lesions**

*Tracheomalacia* results from abnormally soft, undeveloped supporting cartilage of the tracheal rings. This diagnosis should be suspected in patients with a history of stridor that increases over the first few weeks of life and worsens with agitation, supine positioning, and infection. Plain radiographs are usually nondiagnostic, but dynamic studies such as fluoroscopy or ultrafast CT may be helpful.

*Tracheal stenosis* is a congenital anomaly that results from complete tracheal rings. Infants have persistent stridor and respiratory distress. Because the trachea is “fixed,” symptoms worsen with agitation and age.

A *vascular ring* is an anomaly of the aortic arch and related vessels in which a ring is formed that encircles the trachea, esophagus, or both. Examples of “vascular rings” include a double aortic arch, right-sided aortic arch with a persistent left ligament, aberrant right subclavian artery, and a pulmonary sling. These conditions are rare and are often manifested in infancy with a variety of symptoms related to breathing and feeding. However, the nonspecific nature of the infant’s symptoms and the low prevalence of these lesions often result in an initial incorrect diagnosis of croup or URI. In a retrospective review of 38 patients, the diagnosis was made in the first year of life in 87%. Stridor (50%), wheezing (53%), and dyspnea (45%) were the most common initial symptoms, followed by cough (34%), recurrent URI (32%), and dysphagia (32%). Sixty-three percent of these patients had associated cardiovascular anomalies.

This diagnosis should be considered in any infant with persistent, unexplained respiratory and feeding problems. A chest radiograph revealing an abnormal (right-sided) location of the aortic arch may suggest the diagnosis in the emergency department. Definitive diagnosis requires further investigation. Traditionally, a barium esophagogram has been considered to be the single most important diagnostic procedure in patients with complete vascular rings (Fig. 166-8). The need for additional studies such as CT, MRI, angiography, or bronchoscopy should be individualized. Importantly, the common association of congenital cardiac anomalies is a consideration in the workup of these patients.

**Bacterial Tracheitis**

**Principles of Disease.** Bacterial tracheitis (membranous croup, bacterial croup, pseudomembranous croup) is a relatively rare but serious cause of stridor and airway obstruction in children. Bacterial tracheitis was “reintroduced” by Jones and associates in 1979 after a period of almost 4 decades when it seemed to disappear as a clinical entity. It generally affects younger children, with a peak incidence at approximately 3 to 4 years of age. However, bacterial tracheitis has been reported in patients well beyond this age group, thus making it a diagnosis seen in adolescence and young adulthood as well.

The pathogenesis of bacterial tracheitis is severe inflammation of the tracheal epithelium and the production of thick mucopurulent secretions. The lining of the trachea forms a loosely adherent membrane that sloughs into the lumen. Traditionally, *S. aureus* has been the organism primarily responsi-
organisms recovered in tracheal secretions were *S. aureus* (5), *H. influenzae* type b (4), *Moraxella catarrhalis* (2), *Peptostreptococcus* species (4), *Prevotella* and *Porphyromonas* (4), and *Fusobacterium* species (2). Others have reported *S. pneumoniae*, alpha-hemolytic and group A streptococci, and *Candida albicans*.

Bacterial tracheitis is a secondary bacterial infection complicating a preexisting viral infection. In 1983, Edwards and coauthors published two cases of *S. aureus* bacterial tracheitis in which influenza B was also cultured in one case and parainfluenza 2 was demonstrated in the other. In a later series of 46 patients with bacterial tracheitis, concomitant viral respiratory cultures were positive in 72%.

**Clinical Features.** The clinical features of bacterial tracheitis overlap the symptoms of both croup and epiglottitis (Table 166-2). Patients experience a viral prodrome of fever, barky cough, and stridor. These symptoms typically intensify. The child appears toxic, and signs of airway obstruction and respiratory failure may develop acutely. Differentiating bacterial tracheitis from severe croup or epiglottitis on clinical grounds alone can be difficult. In a combined analysis of three studies, the correct initial diagnosis of bacterial tracheitis was made in only 4 of 26 patients. The admitting diagnoses in the remaining 22 patients were viral croup, epiglottitis, and aspiration. In another report of 16 patients with bacterial tracheitis, an initial diagnosis of croup was made in 7 and acute epiglottitis in 2. Features that suggest bacterial tracheitis include a viral prodrome followed by acute decompensation, symptoms atypical for croup (high fever, cyanosis, and severe distress), a poor response to usual treatment of croup (steroids and aerosolized epinephrine), and the presence of both inspiratory and expiratory stridor.

**Diagnostic Strategies.** Evaluation of a toxic-appearing child with bacterial tracheitis should be conducted expeditiously. Laboratory tests are nondiagnostic. The white blood cell count is normal or slightly elevated. Blood cultures are usually negative. Lateral and anteroposterior views of the neck and chest may be helpful. Findings on plain radiographs include subglottic narrowing, a ragged edge of the usually smooth tracheal air column, and a hazy density within the trachea.

cheal lumen. The epiglottis and supraglottic structures appear normal. In addition, the chest radiograph may reveal coexisting pneumonia. Bronchoscopy is both diagnostic and therapeutic and should be performed on an emergency basis. This procedure should allow for visualization of the supraglottic structures and larynx, exclusion of other pathology, suctioning of tracheal secretions and debris, and establishment of an artificial airway.

**Management.** In relatively few cases, severe distress requires immediate intubation and suctioning in the emergency department. Airway management in the setting of the operating room is preferred. These patients require hospital admission, intensive care, supplemental oxygen, fluid resuscitation, and broad-spectrum antibiotics.

Intubation has been required in the majority of patients. In six of eight series, intubation rates exceeded 70%. The remaining two reported intubation rates of only 30%. The investigators postulated that the absence of aspiration pneumonia and older age are factors that may account in part for the decreased need for active airway management in some patients. Overall, recovery is slow. The duration of intubation in patients with bacterial tracheitis is reported to be 4 to 5 days, as opposed to 48 hours for croup and 54 hours for epiglottitis. Reintubation after elective extubation was reported to be necessary in 4 of 10 patients because of recurrence of severe respiratory distress.

Rare complications that have been reported in association with bacterial tracheitis include toxic shock syndrome, septic shock, postintubation pulmonary edema, and acute respiratory distress syndrome.

**Aeroesophageal Foreign Bodies**

**Airway Foreign Body**

**Perspective.** Asphyxia after foreign body aspiration is a common cause of death in children. The majority of cases and deaths occur in toddlers younger than 3 years. A foreign body can lodge in any part of the airway and can move. Round-shaped foods are the most frequently aspirated objects: grapes, raisins, peanuts, and hot dogs. Nonfood objects include a whole host of items. Conformable objects are the most difficult to manage and remove, and balloons, including those made from examination gloves found in physicians’ offices, are the objects most likely to result in death.

In general, objects that pass through the subglottic space will lodge in a bronchus, usually the right main stem bronchus, or in a more terminal part of the airway. Large objects that lodge in the upper airway and trachea tend to cause obvious and dramatic signs of upper airway obstruction: dyspnea, drooling, stridor, and cyanosis. They also carry the worst prognosis.

**Clinical Features.** An upper airway foreign body can cause partial or complete obstruction. A patient who is adequately oxygenated and is moving air should be initially allowed to maintain a preferred position, continue coughing to clear the obstruction, and breathe spontaneously.

Clinical signs of complete obstruction include poor air exchange, ineffective cough, severe distress, and cyanosis. The response to complete obstruction will be determined by the setting and available equipment. Outside a setting in which laryngoscopy and airway equipment are available, relief of a complete obstruction should follow the American Heart Association age-specific guidelines for obstruction by a foreign body.

**Diagnostic Strategies.** In a child with an aspirated foreign body in the upper airway, there is often no time nor is it prudent to obtain diagnostic imaging. In a stable patient, a portable lateral neck radiograph and a chest radiograph may be obtained as long as the patient is allowed to maintain a position of comfort.

**Management.** Basic life support maneuvers to remove a foreign body in children include back blows and chest thrusts in infants and abdominal thrusts in children and adolescents. Choking infants younger than 1 year should receive a series of five back blows delivered between the shoulder blades, followed by five chest thrusts. Chest thrusts should be performed in a manner similar to chest compressions; the thumb encircling technique is preferred in infants. The infant’s head should be held below the trunk. Abdominal thrusts should not be performed in infants because of the possibility of injury to abdominal organs. Blind finger sweeps are not performed in infants or children because this maneuver may push the object further into the airway.

In children older than 1 year, the Heimlich maneuver is used in children who are conscious and chest compressions in children who are unconscious. When performing the Heimlich maneuver, the rescuer places the fist of one hand in the other hand and against the abdomen of the victim. Five thrusts are delivered between the waist and rib cage. The rescuer’s hands should not be placed on the xiphoid. This maneuver is performed in the standing position in a conscious victim. An unconscious child should be placed supine with the rescuer kneeling astride the victim. In the hospital setting, the airway should be open with a jaw thrust and the patient assessed for respirations. If there is no chest rise, assisted ventilation with a bag-mask device (manual resuscitator) is indicated. If there is still no chest rise, laryngoscopy should be performed to visualize and remove the foreign body with pediatric Magill forceps. If the foreign body cannot be seen in the pharynx or larynx, it may be located in the esophagus, where it could be pushing on the soft cartilage of the trachea and causing the obstruction. In this case, basic life support maneuvers may dislodge the foreign body into the mouth where it can be removed. If it appears within the subglottic space or trachea and cannot be removed, basic life support maneuvers may dislodge it into the oropharynx, or an attempt to push it into a main stem bronchus with an endotracheal tube may allow ventilation of the other lung but may result in irreversible airway obstruction. Recruiting additional expertise in the form of an ear, nose, and throat specialist, anesthesiologist, or general surgeon may be valuable.

The emergency physician should undertake emergency needle cricothyrotomy to access the airway in an obstructed patient who cannot be intubated nor bag-mask ventilated. A large intravenous catheter (14–18 gauge) is passed through the midline of the inferior edge of the cricothyroid membrane. When air is aspirated, the plastic catheter is advanced and connected to the adapter of a 3-0 endotracheal tube and then connected to a manual resuscitator. Needle cricothyrotomy kits are also commercially available. Jet ventilation devices or the use of wall oxygen flow may allow for greater ventilation than possible with a self-inflating manual resuscitator. This is generally considered a temporizing measure that allows for oxygenation until another airway can be established.
**KEY CONCEPTS**

- **Retropharyngeal abscess.** A potentially life-threatening emergency in young children with signs of upper airway obstruction or meningismus, a retropharyngeal abscess is often related to oral trauma. It is most frequently caused by *Staphylococcus aureus*, group A streptococci, and anaerobes.

- **Epiglottitis.** In the post-*H. influenzae* type b vaccine era, the typical profile of epiglottitis has changed to include older patients. *Group A Streptococcus* causes the majority of infections; *H. influenzae* type b is the infectious agent in a minority of cases. The clinical features of epiglottitis are usually sufficiently characteristic that diagnostic tests are not necessary to make the diagnosis.

- **Croup.** Viral croup is the most common infection of the upper airway in young children and is often mild. The mainstays of managing moderate to severe croup include vaporized epinephrine and glucocorticoids. These patients can be discharged from the emergency department after a post-treatment observation period of several hours if they remain free of stridor and distress and have access to follow-up care.

- **Bacterial tracheitis.** The clinical features of bacterial tracheitis represent a progression from a viral URI to acute toxicity and marked respiratory distress. *S. aureus* is the most common cause of this infection. Bronchoscopy is both diagnostic and therapeutic and should be performed on an emergency basis.

- **Airway foreign body.** Children with an airway foreign body are managed with basic, followed by advanced, life support procedures for removal of the foreign body. Emergency cricothyroidotomy is reserved for obstructed patients who cannot be intubated or ventilated.

ASTHMA

Perspective

Introduction and Epidemiology

Asthma is the most prevalent chronic disease of childhood, affecting almost 7 million children in the United States. In the past 25 years, childhood asthma prevalence rates have more than doubled. The public health burden posed by this disease, as assessed by emergency department (ED) visits, hospitalizations, and deaths, remains at a historically high level. About 3% of all ED visits among children are for asthma, accounting for 750,000 such visits annually. Similarly, about 3% of all hospitalizations for children are due to asthma, totaling about 200,000 per year. In addition, there are astonishing racial disparities among children with this condition. Compared with white children, black children have a 60% higher prevalence rate, a 260% higher ED visit rate, a 250% higher hospitalization rate, and a 500% higher death rate due to asthma.

Thus, asthma is one of the few chronic diseases of childhood for which there have been increases in prevalence, morbidity, and mortality in recent decades. These trends are occurring despite unprecedented investments in terms of money, preclinical and clinical research, and national focus. The reasons for these trends are no doubt multifactorial and are beyond the scope of this discussion. This portion of the chapter will focus on the recognition, evaluation, and clinical management of children in the ED with acute asthma.

Distinguishing Principles of Diseases

Anatomy and Physiology

Asthma, a lower airway disease marked by bronchoconstriction, mucosal edema, and pulmonary secretions, may lead to respiratory failure if not treated in a timely or effective manner. Important anatomic and physiologic differences exist between children and adults that may hasten the development of respiratory failure, mandating that clinicians quickly recognize and take appropriate measures to reverse respiratory distress.

An upper respiratory infection (URI) associated with copious rhinorrhea, a common trigger of an asthma exacerbation, may significantly increase airway resistance. Further, a small decrease in the internal diameter of the upper airway causes a greater increase in resistance for the young child compared to the adult. In fact, just one millimeter of edema can decrease the cross-sectional area of the infant's airway by 75%.

Regarding the thorax, the young child has a compliant chest wall and horizontally located ribs. These factors limit use of the thorax to increase tidal volume; instead, ventilation is dependent on diaphragmatic movement. However, abdominal distention as might occur with crying or swallowing of air will impede diaphragmatic breathing. With the inability to significantly increase tidal volume, minute ventilation becomes rate dependent, quickly leading to fatigue.

An infant under 12 months of age has an oxygen consumption index that is double that of an adult, due to a higher rate of metabolism. Increased airway resistance and chest wall compliance necessitate more rapid breathing and increased energy expenditure. Increased work of breathing may account for as much as 15% of total oxygen consumption, at a time when oxygenation is poor. As a result, the child will develop hypoxemia quite rapidly in response to respiratory disease. The child with significant respiratory distress and inadequate oxygenation may become bradycardic, leading to cardiopulmonary arrest within minutes, if appropriate interventions are not undertaken.

Clinical Features

Clinical Evaluation

All acutely wheezing children arriving for ED care should be attached to a cardiorespiratory monitor and have oxygen saturation determined by pulse oximetry. If needed, supplemental oxygen should be provided. After this, the clinician may begin the clinical assessment.

History

In evaluating the child with acute wheezing, the treating physician should obtain a concise history, perform a brief and focused physical examination, determine the initial degree of illness, and initiate appropriate therapy. After therapy has begun, a more comprehensive history and physical examination can be conducted. The initial history should include questions regarding the child’s age, duration and severity of symptoms, possible choking episode (foreign body aspiration), and recent medication use. The parents should be able to relate how the severity of this attack compares to that of previous exacerbations. A history of difficulty sleeping, eating, or speaking as a result of this attack suggests a moderate to severe
Physical Examination

The initial focused physical examination of the wheezing child should include obtaining vital signs and assessing the level of consciousness. A child who is anxious, restless, or lethargic may be hypoxicemic. No single asthma score has been universally adopted to assess degree of illness or treatment responses. Most asthma scores include key clinical factors such as respiratory rate, degree of wheezing, inspiratory to expiratory ratio, use of accessory muscles, and oxygen saturation in room air. Such scores can assist in assessing the pre-treatment degree of illness at ED triage, as well as tracking the child’s response to therapy.

For a child with severe disease, wheezing may be audible without a stethoscope or, if aeration is extremely poor, no wheezing may be detected. Asymmetrical wheezing suggests pneumonia, pneumothorax, or the presence of a foreign body. Palpation of the chest and neck may reveal subcutaneous air, associated with a pneumomediastinum or pneumothorax. Following this initial assessment, the remainder of the physical examination may be performed. The most anxiety-provoking aspects of the examination such as otoscopy should be delayed until after treatment is well underway.

Diagonal Strategies

Pulse Oximetry and Arterial Blood Gas

Adjunctive studies such as arterial oxygen saturation measured by pulse oximetry may assist in determining the initial degree of illness. Pulse oximetry is noninvasive, inexpensive, and provides objective data regarding the degree of illness of a wheezing child. The oxygen saturation of any child with respiratory distress should be determined soon after ED arrival and supplemental oxygen should be provided if the oxygen saturation is 92% or less.

With the widespread use of pulse oximetry, physicians rarely need to obtain an arterial blood gas (ABG), especially if the sole purpose is to determine the partial pressure of oxygen. The acquisition of an ABG should be reserved for the child with severe disease to measure the extent of respiratory acidosis and hypercapnia. The timing of this test is important. For a severely ill child requiring admission to the ICU, it may be helpful to obtain this test after ED therapy has been initiated and after a clinical plateau has been reached. ABG results can then be used as a baseline that may be compared to subsequent results during the hospitalization. An apparently “normal” partial pressure of carbon dioxide (PaCO₂) or pH may actually reflect severe disease. For example, a “normal” PaCO₂ of 40 mm Hg in a child with extreme tachypnea and retractions suggests impaired ventilation and impending respiratory failure.

Peak Expiratory Flow Rate

Measuring the peak expiratory flow rate (PEFR) is a means of obtaining an objective assessment of exacerbation severity but it has limited utility in the evaluation of acutely ill children. Young children, in particular, may be unable to properly comply with this testing, and in one study just two thirds of children above age 5 years were able to complete PEFR testing during an asthma exacerbation. Ideally, the PEFR should be determined with the child standing and the best of three attempts recorded. Therefore, moderately to severely ill or younger children may not be able to cooperate with this assessment.

Chest Radiographs

URIs marked by low-grade fever and coughing are common triggers of asthma exacerbations. These signs overlap with those found among children with pneumonia, making it difficult to determine the necessity of obtaining a chest radiograph (CXR) in the evaluation of an acutely wheezing child. No set of predictors has been found that can accurately identify children likely to have abnormalities on CXR. Hyperinflation, interstitial markings, and atelectasis are common radiographic findings that may be seen in a wheezing child, but these should not result in initiating antibiotic therapy or other changes in management. More serious conditions associated with asthma such as pneumonia, pneumomediastinum, or pneumothoraces are much less common. Rarely is an unsuspected diagnosis made on the basis of a CXR in an acutely wheezing child, even if the child has never wheezed before.

It should not be a routine practice to obtain CXRs for all wheezing children, even those who are wheezing for the first time or those who are being hospitalized. CXRs should be considered for those with focal chest findings, fever, extreme distress, or history of choking. Reassessment after treatment to evaluate for the resolution of focal findings may further decrease the need for obtaining a CXR. This selective approach will be more cost-effective and lessen unnecessary radiation exposure and overuse of antibiotics. On the other hand, clinicians may have a lower threshold for obtaining CXRs for infants with first time wheezing because of a slightly greater likelihood of uncovering an anatomic abnormality.

Differential Considerations

Although most children with wheezing have asthma, other conditions must be considered. A differential diagnosis for childhood asthma is listed in Table 167-1. Of these conditions, bronchiolitis, laryngotracheobronchitis (croup), pneumonia, and gastroesophageal reflux are those that clinicians will encounter most often. Bronchiolitis is the one disease that is most commonly confused with asthma. Although the viruses associated with bronchiolitis infect children of all ages, clinical

Young infants with recurrent wheezing, frequent “spitting up” of feed, or failure to thrive should be referred for a diagnostic workup.

**Management**

For purposes of patient management, it is best to stratify children by degree of illness, based on the initial clinical assessment (Fig. 167-1). This will help to ensure the timely initiation of an appropriately aggressive approach for sicker children while minimizing adverse effects from unnecessary therapy among those with milder exacerbations. Of course, during the ED stay, the illness severity may change, making frequent examinations to assess response to therapy essential.

**Mild Exacerbation**

A mild exacerbation is characterized by alertness, slight tachypnea, expiratory wheezing only, a mildly prolonged expiratory phase, minimal accessory muscle use, and an oxygen saturation of greater than 95%. Children who are able to provide a PEFR should have a value greater than 70% of personal best. Patients with a mild exacerbation, especially those who were not receiving any asthma therapy prior to the ED visit, will usually require SABA therapy only. The Expert Panel of the National Heart, Lung, and Blood Institute (NHLBI) recommends that patients receive therapy every 20 minutes in the first hour of care. Often, children with mild exacerbations improve promptly with just one or two SABA treatments. Many of these patients are managed without systemic corticosteroids. However, systemic corticosteroids may be given to those who are already undergoing a course of treatment with them prior to ED arrival or to those who do not respond promptly to SABA therapy (see later section on Moderate Exacerbation).

Due to its rapid onset of action, relatively long duration of action, and good safety profile, racemic albuterol has become the SABA of choice to treat children with acute asthma. Options for mode of delivery include small-volume nebulizers (NEBs) or metered dose inhalers with spacers (MDI-Ss), and recent studies have assessed the use of levalbuterol in this setting.

**Nebulizers versus Metered Dose Inhalers with Spacers.** There is considerable debate regarding the optimal method to deliver SABAs to children with acute asthma. About three fourths of pediatric emergency medicine physicians report using NEBs to administer SABAs, regardless of illness severity. NEBs provide a passive means of receiving aerosolized medication. Precise coordination between respiration and aerosol delivery is not needed, and medications such as anticholinergics as well as humidified oxygen may be delivered concurrently with the SABA. However, delivery is inefficient, with only about 10% of the drug in the reservoir delivered to the small airways. In addition, administration takes about 10 minutes, increasing respiratory therapy time and costs, and an external power source is needed, limiting portability.

On the other hand, spacers used with MDIs provide a reservoir of medication that is available to be inhaled. Therefore, precise coordination between actuation and inhalation is not needed and there is no need for breath-holding. Drug deposition in the oropharynx and systemic absorption is reduced with the employment of a spacer. The decreased administration time associated with MDI-S use may result in reduced costs. The portability of MDI-S allows older children to use them during the school day. Face mask–equipped spacers are available for children too young to use the spacer’s mouth-
Emergency department management of acute asthma.

Racemic Albuterol versus Levalbuterol. Another consideration in the use of SABAs is the potential role of levalbuterol. Racemic albuterol is an equal mix of the active R-albuterol and the inactive S-albuterol. R-albuterol produces bronchodilation as well as side effects such as tachycardia and tremors. S-albuterol was long thought to be inert. However, there is some evidence that S-albuterol may increase reactivity to histamine, have proinflammatory effects, and exhibit “characteristics of a typical contractile agent.”<sup>36-42</sup> Further, there seems to be preferential retention of S-albuterol in the lungs of healthy volunteers<sup>40-42</sup>; this may account for diminished effectiveness with frequent dosing. Levalbuterol is pure R-albuterol without the S-component. In theory, levalbuterol should be more effective than racemic albuterol at half the dose because there are no competing harmful effects from the S-isomer.

Studies assessing the use of levalbuterol to treat children with acute asthma have not consistently demonstrated this theoretical advantage. In the first of these clinical trials, levalbuterol (1.25 mg) was compared with racemic albuterol (2.5 mg) in the ED treatment of over 500 children with acute asthma.<sup>43</sup> The use of levalbuterol was associated with a

decreased need for hospitalization. However, the baseline hospitalization rate in this study was quite high even though patients with all degrees of illness severity were enrolled. Subsequently, three other randomized trials comparing the ED use of the two drugs have failed to find a levalbuterol benefit.47–49 These three studies analyzed children with a wide range of illness severities and baseline hospitalization rates and used various outcome measures such as asthma scores, pulmonary function tests, and hospitalization rates. Racemic albuterol was demonstrated to be as effective as levalbuterol under each of these circumstances.

To date, there are no published data assessing the use of continuously nebulized levalbuterol in the ED treatment of children with asthma. The acquisition cost of levalbuterol is over 10 times greater than racemic albuterol.50 Until there are more compelling data to demonstrate conclusively that the additional costs of levalbuterol are offset by the need for fewer nebulizations, decreased length of ED or hospital stay, or decreased need for hospitalization, racemic albuterol should remain the drug of choice for children with acute asthma exacerbations.

Disposition. Most children with a mild exacerbation will be able to be discharged home. Those sustaining clinical improvement 60 minutes after the most recent SABA treatment may still be discharged. SABAs should be continued for the next 3 to 10 days. If systemic corticosteroid therapy was administered in the ED, it should also be continued for 3 to 10 days. Children should continue all other asthma controller medications, including inhaled corticosteroids (ICS).

For those who are not already receiving ICS, it is unclear if prescribing them at ED discharge leads to improved short-term outcomes. Among adult asthmatics discharged from the ED after acute asthma exacerbations, the addition of inhaled flunisolide did not lead to improved outcomes.50 Of note, though, compliance with the inhaled medication was low and many patients were lost to follow-up. On the other hand, adults randomized to inhaled budesonide following ED discharge had a marked decrease in relapse rates, frequency of SABA use, and asthma symptoms.52 A review concluded that there is “insufficient evidence that ICS provide additional benefits” when added to systemic corticosteroids at ED discharge.53 Pediatric emergency medicine physicians rarely prescribe ICS at ED discharge, even to children who have persistent asthma.54

Rather than prescribing ICS to prevent ED relapse, emergency physicians should consider longer-term goals for those with persistent disease. National guidelines state that ICS are the medications of choice when initiating long-term controller therapy for children with persistent asthma.55 Further, these drugs are safe and well tolerated at recommended doses. Longitudinal studies show that daily use of ICS may decrease growth velocity, but these changes are small and reversible.56,57 Therefore, ED physicians should identify children who, during the preceding month, have had frequent asthma symptoms, nighttime awakenings, and the need for frequent use of SABAs for asthma control. As stated by national asthma guidelines, initiation of ICS therapy at ED discharge “should be considered” for these patients.55 Those already taking low doses of daily ICS may benefit from an increase in dosing.

In addition to prescribing medications, ED physicians should also provide asthma education at discharge. Some EDs employ the use of a video or DVD to provide standardized information to families while they undergo ED therapy. This education should include how to identify and avoid asthma triggers, a written asthma action plan explaining proper steps to take in response to an asthma flare, review of discharge medications, and proper MDI-S use. Also, follow-up asthma care within 1 to 4 weeks should be arranged.

Summary. For children with mild asthma exacerbations, racemic albuterol should be administered every 20 minutes, as needed (Fig. 167–1). Most children will respond promptly to therapy and be well enough to be discharged home after 1 or 2 treatments. Systemic corticosteroids may be considered for those who exhibit a suboptimal response to SABAs (see later section on Moderate Exacerbation). NEBs or MDI-S are each reasonable options to deliver SABAs intermittently. Table 167–2 lists recommended doses for SABAs and other asthma medications in the ED, and Table 167–3 provides a recommended strategy for SABA administration. Rather than base the method of delivery on the issue of efficacy, clinicians should assess other factors. The answers to questions such as the number of treatments a child is likely to need, the anticipated cooperation with a given delivery method, the need to deliver concurrent medications, and costs will help to guide decision-making.

Moderate Exacerbation

Children who are alert but very tachypneic with wheezing throughout expiration, an inspiratory:expiratory ratio of 1:2, and significant use of accessory muscles are experiencing a moderate asthma exacerbation. Typically, the oxygen saturation will be 92 to 95% and the PEFR will be 41 to 70% of the personal best. As with children experiencing more mild attacks,
the cornerstone of therapy is aggressive SABA therapy. In addition, other medications such as ipratropium bromide (IB) and corticosteroids should be added and consideration should be given to delivering SABAs continuously.

Anticholinergics. Stimulation of airway cholinergic receptors results in reflex bronchoconstriction, which may be blocked with the use of anticholinergic agents such as IB. This medication is available as an MDI as well as a solution for nebulization that may be mixed directly with racemic albuterol. The MDI formulation should not be given to patients with allergy to peanut or soy because it contains soya lecithin; this is not a concern with the solution for nebulization.

Studies have shown that use of SABAs with IB is more effective than SABAs alone. In a randomized, double-blind clinical trial, three doses of IB administered concurrently with the first three SABA treatments were shown to be superior to just one dose of IB. In another study, over 400 children were randomized to receive racemic albuterol and prednisone alone or that therapy plus IB. Those judged to be moderately ill did not experience an IB benefit. However, among those with an initial PEFR less than 50% predicted, the use of IB resulted in a significantly lower hospitalization rate. A recent systematic review and meta-analysis compared the use of SABAs plus anticholinergics with SABAs alone among children older than 18 months. In the 16 trials assessed, combination therapy was associated with significantly lower hospitalization rates and improvements in asthma scores and pulmonary function testing. These investigators concluded that multiple doses of IB added to SABAs should be standard treatment for children with moderate to severe asthma exacerbations.

Clinical benefits following IB use may be delayed for up to 60 minutes. However, it is inexpensive and since less than 1% is absorbed systemically, it is virtually free of adverse effects. IB should be administered to children with moderate exacerbations. Three doses may be mixed with racemic albuterol and delivered concurrently and continuously by NEB in the first hour of care (see Table 167-3). This means of administration, although not superior to delivery by MDI-S, will help to ensure compliance with the goal of the equivalent of three NEB treatments in the first hour of care. Alternatively, four to eight puffs of IB may be given every 20 minutes in the first hour of care, but these children will also need to receive a substantial number of puffs of SABAs and, as clinicians care for other patients, there may be delays in receiving appropriately aggressive therapy.

Systemic Corticosteroids. There is compelling data to show that the prompt use of corticosteroids can decrease the need for hospitalization and that they should be used routinely for patients with moderate disease. Clinicians must decide the optimal agent and route of administration.

Oral versus Parenteral. Two early clinical trials established the efficacy of parenterally administered corticosteroids in the ED. Compared with those treated with placebo, adults treated with intravenous (IV) methylprednisolone had a lower hospitalization rate, as did children treated with intramuscular (IM) methylprednisolone. Scarfone and colleagues were the first to demonstrate the efficacy of orally administered corticosteroids in this setting. Children treated with frequent SABAs and oral prednisone had a reduced need for hospitalization compared to those treated with SABA therapy alone. Further, a meta-analysis determined that compared to placebo, oral corticosteroids were effective in reducing the need for hospitalization among children with acute asthma exacerbations.

There have been few clinical trials directly comparing oral and parenteral therapy. In one small study, there were no differences in any outcome measures for children in the ED with moderate to severe asthma who were treated with equal doses of either IV or oral methylprednisolone. The most recent NHLBI guidelines recommend using oral corticosteroids since this form of administration is less invasive and the benefits seem to be equivalent to parenteral therapy. Further, oral corticosteroid therapy is inexpensive, the drugs are rapidly and completely absorbed, and this mode of administration provides the potential for out-of-hospital administration either at home or in a physician’s office.

Prednisone versus Dexamethasone. As with SABAs, clinicians have a choice in the specific corticosteroid to be used. Oral prednisone has been the drug of choice in this setting. Significant clinical benefits begin 2 hours after administration, are most pronounced among the sickest children, and result in a decreased need for hospitalization. Dexamethasone phosphate may be given orally or parenterally and has a substantially longer (36–72 hours) half-life than prednisone (18–36 hours). Investigators recently treated children in the ED with either 0.6 mg/kg of dexamethasone or 2 mg/kg of prednisone in a randomized fashion. Those in the dexamethasone group were provided one additional dose to take the following day, while those in the prednisone group were given a prescription for 4 additional days of prednisone. There were no differences in hospitalization or relapse rates or symptom persistence. Significantly fewer dexamethasone patients vomited the study drug in the ED and reported noncompliance with it after ED discharge. Of note is that Orapred, a more palatable form of oral prednisone, was not used in this study.

These data suggest that either dexamethasone or prednisone may be used in the treatment of moderately ill children with acute asthma. Given that clinical benefits from corticosteroids are delayed and that all moderately ill children will require corticosteroids whether or not they require hospitalization, they should be administered as soon as possible after ED arrival in an attempt to hasten clinical improvement and perhaps prevent the need for hospitalization. Since SABAs are administered by inhalation and corticosteroids may be given orally, most children with a moderate asthma exacerbation can be managed without the insertion of an IV line. This avoids unnecessary pain and anxiety, as well as the delays in drug administration associated with IV line insertion. IM therapy is a reasonable option for children who vomit orally administered corticosteroids yet do not require an IV line for other reasons.
Inhaled Corticosteroids. The use of ICS for the ED treatment of acute asthma is an area of ongoing research. In three clinical trials, ICS were compared to oral prednisone in the ED setting. Scarfone and colleagues treated children with either nebulized dexamethasone or oral prednisone. The two groups had similar rates of hospitalization, although there was a trend toward greater rate of improvement among the dexamethasone-treated children. A potential limitation to the widespread use of nebulized dexamethasone is that it contains sodium bisulfite, a preservative that may induce wheezing among allergic individuals. Budesonide is an ICS that has a high topical activity and low systemic absorption and is effective in the treatment of children with croup. Investigators from India found that three nebulized doses of budesonide was superior to one dose of prednisone. In another trial, fluticasone-treated children were more likely to be hospitalized and experienced a significantly smaller degree of improvement compared with those treated with prednisone. Finally, investigators determined that children treated in the ED with inhaled triamcinolone had lower hospitalization rates and relapse rates compared to those treated with either prednisone or IV corticosteroids.

Rather than replacing systemic corticosteroids, other investigators have assessed whether or not the addition of ICS to systemic therapy results in clinical benefits; however, few such studies have been performed in children and few have assessed the need for hospitalization. Thus, the niche for ICS in the ED treatment of acute asthma is still being defined. Additional areas for further investigation include determining the optimal agent, the proper dose, the appropriate mode of delivery, and defining the patient population most likely to benefit from this therapy. At this time, there is no proven role for the routine use of ICS in the ED setting. Due to its greater bioavailability and proven benefits, moderately ill children should receive systemic corticosteroid therapy.

Intermittent versus Continuous. Children requiring very frequent intermittently nebulized albuterol may benefit from receiving albuterol continuously instead. In one clinical trial among asthmatic children, patients were randomized to receive the same total dose of albuterol nebulized either intermittently or continuously, over 2 hours. Those in the continuous group had a greater mean improvement in their asthma scores and significantly less respiratory therapy time, although there were no differences in mean PEFR or admission rates. A systematic review found that those treated with continuously nebulized SABAs had lower rates of hospitalization, greater improvements in pulmonary function tests, and similar rates of adverse events compared with those treated intermittently.

Perhaps the greatest advantage of continuous over intermittent therapy is one of a practical nature: it allows greater compliance with the goal of delivering the equivalent of three intermittent albuterol treatments in the first hour of care. In addition, this method will result in less respiratory therapy time and costs, has been shown to be safe, and may benefit the sickest patients the most. On the other hand, young children may not tolerate a face mask for prolonged periods.

Many clinicians find it helpful to determine the total of racemic albuterol that would be delivered if three treatments were to be given intermittently over an hour, place that total dose in the NEB reservoir, and administer it continuously over an hour. Alternatively, a dose range may be used based on the child’s weight (see Table 167-2).

Summary. A suggested approach to the management of children with moderately acute asthma is as follows. Supplemental oxygen should be provided if the initial oxygen saturation is 92% or less in room air. Albuterol and IB should be administered continuously by nebulization for 1 hour (see Fig. 167-1). This will ensure that an appropriate amount of each is delivered in the first hour of ED care. As soon as possible after ED arrival, a single dose of either oral prednisone or dexamethasone should be given. IM dexamethasone is an option for children who vomit the initial oral corticosteroid dose within 15 minutes of its administration or who vomit repeated doses.

After 1 hour of therapy, a clinical reassessment should be made; evaluation at this time is better than the initial assessment at predicting the need for hospitalization. At this point, patients can generally be grouped into one of three categories: markedly improved, not improved or worse, or slightly improved. Children who are markedly improved may be observed without SABAs to ensure that there is no clinical deterioration. It is wise to delay a disposition decision until at least 60 minutes after the most recent SABA treatment so that a clinical relapse may be noted. In making the disposition decision, the clinician must determine the patient’s physical examination findings and also consider the frequency of prior hospitalizations and ED visits and issues such as compliance and support systems. The medications and education to be provided at ED discharge are the same as outlined for those with a mild exacerbation.

Children who remain moderately ill after the first hour must continue to be treated aggressively with SABAs, either continuously or with frequent administration of intermittent therapy. If after 2 hours objective and subjective measures reveal that the degree of respiratory distress is unchanged or worse, then hospitalization is warranted. On the other hand, there will be a subset of patients who demonstrate some degree of clinical improvement at the 2-hour assessment but are not yet well enough to be sent home. One study showed that among prednisone-treated children who would have been hospitalized after 2 hours of ED therapy, less than half were actually hospitalized when aggressive SABA therapy was continued for an additional 2 hours and none returned to the ED within 48 hours of discharge. Presumably, the onset of prednisone’s effects allowed these children to avoid hospitalization. Therefore, continuing to treat such children with SABAs for a total of 3 to 4 hours, perhaps in an ED observation area, would be expected to avoid the need for many hospitalizations.

Severe Exacerbation

A severe exacerbation is characterized by restlessness or lethargy, extreme tachypnea and tachycardia, wheezing that is audible without a stethoscope, an inspiratory:expiratory ratio exceeding 1:2, significant use of accessory muscles, and an oxygen saturation less than 92%. Some older children with a severe exacerbation may have bradypnea because of a prolonged expiratory phase and wheezing may not be audible if aeration is markedly decreased. The PEFR will typically be less than 40% predicted, although most children will be too ill to use the peak flow meter.

Figure 167-1 provides an outline for the approach to managing severely ill children. They should be attached to a cardiorespiratory monitor and blood pressure cuff with continuous monitoring of oxygen saturation by pulse oximeter. As with the moderately ill child, supplemental oxygen and continuously nebulized albuterol and IB should be provided soon after arrival. To achieve an oxygen saturation of 95% or greater, it may be necessary to employ a non-rebreathing face mask. Severely ill children may be too sick to tolerate oral medications and will likely need an IV catheter for other indications. Therefore, an IV line should be established as soon as possible and a dose of methylprednisolone given.
**Subcutaneous or Intramuscular Therapy.** For children with very poor inspiratory flow, nebulized SABAs may not be effectively delivered to the smallest airways. Short inspiratory time, prolonged expiration, and low inspiratory pressures will impair delivery of inhaled medications. Here, subcutaneous (SC) or IM terbutaline or epinephrine should be used, especially if an IV line is yet to be established. Terbutaline may be preferable because it is a more selective agent with fewer side effects such as tremors, vomiting, or palpitations. Very ill anxious young children who are uncooperative with the inhalation treatments may also benefit from this therapy. There are no data to suggest one mode of administration is superior to the other, although IM therapy is recommended for children with bronchospasm due to anaphylaxis.87 SC or IM therapy may be repeated every 10 to 15 minutes, as needed.

**Magnesium Sulfate.** There is accumulating evidence that magnesium sulfate may benefit adults and children with severe asthma. Recent meta-analyses determined that use of magnesium resulted in improved outcomes for both adults88 and children.89 In two separate trials, children with a suboptimal response to initial SABA therapy who were randomized to receive magnesium had significantly greater improvements in pulmonary function studies compared to those treated with placebo.90,91 In contrast, Scarfone et al conducted a randomized, controlled trial assessing the use of 75 mg/kg of magnesium in asthmatic children.92 They sought to determine if magnesium was efficacious as a component of initial therapy for children with moderate to severe exacerbation, without waiting to judge response to early albuterol therapy. No magnesium benefits were found for this population.

Magnesium is inexpensive and has minimal adverse effects.93 The most common adverse effect is hypotension; this may be avoided by infusing the dose over 20 minutes. The most recent NHLBI guidelines recommend the consideration of magnesium for select patients; this represents a key difference from prior reports. At this point, existing literature indicates that magnesium should be considered for moderately ill patients who have a suboptimal response to SABAs, IB, and corticosteroids as well as for all severely ill children.

**Intravenous Short-Acting Beta2-Agonists.** The NHLBI guidelines conclude that there are insufficient data to make recommendations regarding the use of IV SABAs.2 Similarly, a recent systematic review of randomized, controlled trials failed to support this practice.94 However, of the 15 studies included, just 3 were performed in children and just 3 assessed the combination of IV and nebulized SABAs compared to nebulized SABAs alone.95-97 Rather than definitively demonstrating lack of efficacy, these data highlight the need for more and larger clinical trials.

Potential adverse effects from the use of IV SABAs are substantial and include dysrhythmias, hypertension, and hypokalemia. Due to the concern for toxicities, there is no role for initiating therapy with IV SABAs, even for severely ill children. However, for those who are poorly responsive to the interventions outlined above, with impending respiratory failure, the risk-benefit ratio shifts toward their use.

**Heliox.** Heliox is a low-density mixture (often in a 70:30 ratio) of helium and oxygen that results in less turbulent flow through narrowed airways. Theoretically, its use is associated with decreased work of breathing, less respiratory muscle fatigue, and a lower likelihood of ventilatory failure. In one trial, children with acute severe asthma treated with heliox had a significantly greater decrease in pulse paradoxus and dyspnea index, and increase in PEFR, compared to others.98 A more recent study compared the use of heliox versus oxygen alone to deliver continuously nebulized SABAs.99 At 240 minutes, children in the heliox group had greater improvement as assessed by decreased asthma scores and need for hospitalization. However, after reviewing 10 clinical trials assessing the use of heliox, investigators concluded that there is insufficient evidence to support the use of heliox for all patients with asthma,100 although it may be considered for severely ill children who are not responding to more conventional therapy.

**Mechanical Ventilation.** When making decisions about the need for mechanical ventilation of the severely ill patient, one must assess the entire clinical picture, including duration of wheezing, illness severity, response to therapy, as well as ABG results. Making this decision based on the ABG results alone should be discouraged. For example, the child with a pH of 7.10 and a PaCO2 of 55 who shows marked improvement with IV SABA therapy may not require ventilatory assistance, yet the one with a pH of 7.18 and a PaCO2 of 50 who appears fatigued and is not responding to therapy probably does. Ketamine is a bronchodilator and is the drug of choice for sedation and analgesia of the asthmatic child who requires intubation.

With mechanical ventilation, air trapping with resultant pneumothorax is a major concern. Permissive hypercapnia is a term used to describe a strategy of minimizing tidal volumes and respiratory rate in order to minimize peak pressures. A degree of hypercapnia is accepted and may be treated with sodium bicarbonate. Enough expiratory time must be allowed for air exit from the lungs.

There are many potential therapies that are not recommended for the treatment of acutely ill asthmatic children. These include methylxanthines such as aminophylline, the routine use of antibiotics in the absence of known bacterial infection, aggressive hydration, chest physiotherapy, mucolytics, sedation, and noninvasive ventilation.2

**Summary**

Asthma is one of the few diseases in which there have been increases in prevalence, morbidity, and mortality in the past 2 decades. More than ever, physicians need to be vigilant in the recognition and treatment of children with acute asthma. In all cases, appropriate doses of albuterol should be given promptly and early use of multidose IB and corticosteroids is indicated for those who are moderately or severely ill. Aggressive use of SC or IM terbutaline, continuously nebulized albuterol, and magnesium is warranted for those who are severely ill, while IV SABAs are reserved for those not responding to the above therapy.

### BRONCHIOLITIS

**Perspective**

**Background**

Bronchiolitis is an acute infectious disease that results in inflammation of the small airways in children younger than 2 years. This process manifests clinically as wheezing and increased work of breathing along with the typical signs and symptoms of a URI. Nearly all children are affected by the viruses that cause bronchiolitis at least once during their first 2 years of life, but it is more common for infants younger than 12 months to develop clinical bronchiolitis.

**Epidemiology**

Bronchiolitis is a seasonal disease, with most cases occurring between November and April in temperate climates. It
accounts for approximately 3% of all ED visits in the United States. Overall, approximately 19 to 27% of children presenting to an ED with bronchiolitis are admitted for inpatient management. This disease accounts for more than 20% of acute care hospitalizations for children younger than 1 year, and the total cost for all bronchiolitis-related hospitalizations is more than $500 million per year. Hospitalization rates vary depending on many factors, and these rates have increased dramatically over the past 2 decades. In the United States, Hispanic children and those of Alaskan or American Indian descent are more likely to be admitted to the hospital after presenting with bronchiolitis. Males and younger infants are also more likely to need admission. Other factors that seem to be associated with hospitalization are poverty, household crowding, exposure to environmental tobacco smoke, and day care attendance. Clearly, underlying chronic medical conditions, such as congenital heart disease or chronic lung disease, lead to a more severe course in patients with this disease.

Bronchiolitis is rarely fatal, with an average mortality rate of 2.0 per 100,000 live births in the United States. Low birth weight (<2500 g), low 5-minute Apgar score, high birth order, and young maternal age are all associated with an increased risk of death. Breast-feeding, on the other hand, appears to be associated with a less severe clinical course.

**Distinguishing Principles of Disease**

**Etiology**

Many viruses are implicated as the underlying cause for bronchiolitis. Respiratory syncytial virus (RSV) is the most common agent identified in children diagnosed with this disease, estimated to cause up to 70% of cases in previously healthy children. Other viruses commonly isolated are parainfluenza, human metapneumovirus, influenza, adenovirus, and rhinovirus. Most respiratory viruses that cause bronchiolitis in children are transmitted from one host to another via fomites spread from hand to nose or via droplets produced by sneezing or coughing of respiratory secretions. Shedding of the virus often begins prior to the onset of significant clinical symptoms and can continue for 2 to 3 weeks in an immunocompetent infant. The typical incubation period is 2 to 8 days from the time of initial contact. In an infected patient, viral replication often begins in the epithelial cells of the upper airway before spreading to the mucosal surfaces of the lower respiratory tract. The infected epithelial cells are generally destroyed by lysis or apoptosis, which results in the desquamation of these cells and release of host inflammatory mediators. Affected lungs demonstrate epithelial cell necrosis, monocytic inflammation and edema of the peribronchial tissues, and mucus and fibrin plugging of the distal airways upon histologic examination. These findings translate into the clinical findings of wheezing and lower airway obstruction in an infant with bronchiolitis. Younger infants, whose distal airways are of smaller caliber and whose immune systems lack active immunity to most respiratory viruses, are prone to more severe clinical symptoms. Severe lower airway obstruction leads to air-trapping and atelectasis, resulting in mismatched ventilation and perfusion and hypoxemia. In addition, younger infants are at increased risk for fatigue, leading to hypercarbia and respiratory failure.

**Pathophysiology**

Typically, infants with bronchiolitis are less than 12 months of age and present during the winter months. The first symptoms are generally those of an upper respiratory infection, such as nasal congestion and copious rhinorrhea. This is followed within a few days by development of a tight cough, often associated with difficulty feeding. Some parents will report the presence of audible wheezing as well. A history of fever is common, though not universal, with one study reporting fever in approximately one third of patients admitted with bronchiolitis. Very young infants may present with a history of apnea, and this may precede the onset of typical symptoms of respiratory infection. It is essential to ascertain information regarding the infant’s hydration status, including the amount and frequency of oral intake, urine output, vomiting, and diarrhea.

A child’s past medical history is important as well. Specifically, comorbidities such as congenital heart disease, chronic lung disease, or prematurity can significantly impact the clinical course of bronchiolitis. A past history or family history of wheezing or atopy may provide clues in differentiating bronchiolitis from asthma, particularly in the older infant. Other elements of the patient history that may be helpful are whether the child attends day care or if there are household contacts with respiratory symptoms.

**Clinical Features**

**Patient History**

Typically, infants with bronchiolitis are less than 12 months of age and present during the winter months. The first symptoms are generally those of an upper respiratory infection, such as nasal congestion and copious rhinorrhea. This is followed within a few days by development of a tight cough, often associated with difficulty feeding. Some parents will report the presence of audible wheezing as well. A history of fever is common, though not universal, with one study reporting fever in approximately one third of patients admitted with bronchiolitis. Very young infants may present with a history of apnea, and this may precede the onset of typical symptoms of respiratory infection. It is essential to ascertain information regarding the infant’s hydration status, including the amount and frequency of oral intake, urine output, vomiting, and diarrhea.

A child’s past medical history is important as well. Specifically, comorbidities such as congenital heart disease, chronic lung disease, or prematurity can significantly impact the clinical course of bronchiolitis. A past history or family history of wheezing or atopy may provide clues in differentiating bronchiolitis from asthma, particularly in the older infant. Other elements of the patient history that may be helpful are whether the child attends day care or if there are household contacts with respiratory symptoms.

**Physical Examination**

As in any pediatric patient, an assessment of vital signs and general appearance is crucial to the evaluation of an infant with bronchiolitis. Common vital sign abnormalities include fever, tachycardia, tachypnea, and hypoxia. Pulse oximetry is noninvasive, inexpensive, and provides objective data regarding the degree of illness of a wheezing child. The oxygen saturation (Sao2) of any moderately or severely ill infant should be obtained soon after ED arrival as an adjunct to the physical examination. With the use of pulse oximetry, an ABG is generally unnecessary to assess a patient’s oxygenation. Thus, the acquisition of an ABG should be reserved for those with severe disease to measure the extent of hypercarbia and respiratory acidosis. Irritability or lethargy may be present, especially in those infants with more severe disease. Nasal flaring and retractions are visible signs of respiratory distress that may be present. Lung auscultation often reveals decreased air movement, rales, rhonchi, wheezing, and an increased ratio of expiratory to inspiratory times. Using these physical examination findings, the clinician may stratify patients into mild, moderate, and severe categories of disease (Table 167-4).

The combination of poor feeding and increased insensible fluid losses often impacts an affected infant’s hydration status. A careful assessment of the anterior fontanel, mucous membranes, and skin turgor can assist in determining whether an infant is dehydrated.

**Complications**

Clinicians caring for children with bronchiolitis need to understand the typical course of the disease, both for their ability to accurately diagnose and manage these patients and to advise parents about the recovery phase. The worst phase of the illness that may necessitate hospitalization generally occurs in the first few days, and median length of hospital stay has been reported to be between 2 and 3 days. However, the entire course of illness can last much longer, with a median duration of 12 days. Coughing and noisy breathing, in particular, can last for more than 4 weeks.
Bacterial acute otitis media (AOM) is the most common condition associated with bronchiolitis, with a prevalence of up to 60%. The bacterial pathogens are similar to those recovered in other children with AOM; thus, it should be treated according to standard recommendations. Other concurrent bacterial infections are rare. In one study of more than 2000 children hospitalized with RSV bronchiolitis, approximately 1% also had a urinary tract infection (UTI). Pathologic bacteremia and meningitis were not found in any of these patients. Similar rates of UTI without bacteremia are found in febrile children with clinical bronchiolitis, with or without documented RSV infection. Infants less than 8 weeks old with fever and bronchiolitis present a unique dilemma for ED clinicians. The rate of serious bacterial infections (SBIs), defined as UTI, bacteremia, bacterial meningitis, or bacterial enteritis, among all febrile infants less than 8 weeks of age is reported to be up to 12%. However, in infants with documented RSV infection or clinical bronchiolitis at the time of ED presentation, the rate of SBI is substantially lower. In a large, prospective, multicenter study, Levine and colleagues reported that 7% of febrile infants less than 61 days of age who were RSV positive had a concurrent SBI, compared with 12.5% of those who were RSV negative. Of the patients with SBIs, most (82%) had a UTI. Bacteremia was rare and only occurred in infants less than 1 month of age. None of the RSV-positive infants had bacterial meningitis. As a result, most would advocate performing a workup for UTI in febrile infants between 1 and 2 months of age who are known to be RSV positive or have clinical bronchiolitis. Additional testing to obtain cultures of cerebrospinal fluid and blood may be done selectively. Similarly, these infants may not require empiric antibiotic therapy for presumed SBIs. On the other hand, in the first month of life, all febrile infants should undergo testing to evaluate for SBIs and be empirically treated with antibiotics regardless of RSV status.

Apnea is commonly reported in young infants with bronchiolitis, especially those who are admitted for inpatient management. Eight percent of admitted patients have a history of apnea, and nearly 3% will develop apnea during the hospital stay. Risk factors for developing in-hospital apnea include age less than 1 month in full-term infants, postconceptional age less than 48 weeks in preterm infants, and a history of apnea prior to admission. The absence of all of these risk factors has a high negative predictive value for the development of in-hospital apnea.

The long-term outcomes after bronchiolitis have also been examined extensively. It is clear that those who experience the disease in infancy have a higher prevalence of lower respiratory diseases, including asthma, in adolescence and adulthood. Whether there is a causal relationship remains undetermined.

### Differential Considerations

Asthma is the condition that has the most clinical overlap with bronchiolitis. Physical examination findings alone cannot distinguish the two. Younger age, presentation during winter months, antecedent URI symptoms, and the absence of prior or family history of atopic disease and wheezing all suggest bronchiolitis as the cause of wheezing in an individual patient. Some infants will have clinical features consistent with both conditions. For example, a 12-month-old may present in July with a URI and wheezing for the first time. For this child, a clinician may choose to initiate therapy for acute asthma. A complete discussion of other conditions that must be differentiated from bronchiolitis is included earlier in this chapter and in Table 167-1.

### Diagnostic Strategies

Bronchiolitis should be diagnosed primarily on the basis of history and physical examination. Viral diagnostic testing can be performed on nasopharyngeal secretions using enzyme-linked immunosorbent assays, indirect fluorescent antibody detection, polymerase chain reaction, or viral culture. Generally, this is not warranted for those patients for whom outpatient management is sufficient. However, identifying a viral respiratory pathogen can be useful in certain situations. For example, if test results can be obtained rapidly, identifying a viral etiology may eliminate the need for further laboratory evaluation for infants who present with fever. In addition, having a specific viral diagnosis can allow for the appropriate cohorting of patients admitted for inpatient management, thus decreasing nosocomial transmission among patients and staff. Providers should exercise caution and droplet precautions until the causative viral agent is identified.

There is tremendous variability in the use of diagnostic imaging; in one series, a CXR was obtained for more than 70% of infants hospitalized with bronchiolitis. In children with clinical findings that are typical for bronchiolitis, however, radiographic imaging is rarely necessary. Hyperinflation, atelectasis, and peribronchial cuffing are the findings most commonly associated with this disease. In ambulatory patients with acute lower respiratory infections, obtaining a CXR does not affect clinical outcome, and this practice has been associated with increased usage of unnecessary antibiotics. Further, the likelihood of a CXR revealing findings inconsistent with the clinical diagnosis of bronchiolitis is less than 1%. Diagnostic imaging may be helpful in patients with severe distress, significant hypoxia, or an atypical presentation or clinical course. In summary, as recommended by the American Academy of Pediatrics (AAP) Subcommittee on Diagnosis and Management of Bronchiolitis, “clinicians should diagnose..."
bronchiolitis and assess disease severity on the basis of history and physical examination. Clinicians should not routinely order laboratory and radiologic studies for diagnosis.\textsuperscript{138}

**Management**

**Therapy**

While the diagnosis of bronchiolitis is fairly straightforward, the management of children with the disease often presents clinicians with confusing and controversial dilemmas. The literature is often contradictory, making it difficult to reach a consensus. As a result, there exists wide practice variation in the management of bronchiolitis.\textsuperscript{139-141} However, it is clear that a consistent, evidence-based approach to this disease can lead to more efficient and effective care.\textsuperscript{130,142-145} Supportive care, such as providing hydration and supplemental oxygen, is the cornerstone of therapy for affected children.\textsuperscript{138} A management strategy, stratified by the patient’s initial degree of illness, is outlined in Figure 167-2.

SABAs are the treatment of choice for children with wheezing due to asthma. However, the evidence supporting their use in wheezing caused by bronchiolitis is less favorable than for asthma. In a recent meta-analysis of 22 clinical trials, a small short-term benefit in clinical score was observed for children with bronchiolitis treated with SABAs. This treatment had no significant effect on rates or duration of hospitalization. While rare, adverse effects such as tachycardia, decreased oxygen saturation, flushing, and hyperactivity occurred more frequently in children treated with SABAs.\textsuperscript{146} Thus, the AAP does not recommend the routine use of SABAs for bronchiolitis; instead, clinicians should consider a trial of such medications to determine if a patient has a positive clinical response.\textsuperscript{138}

Similar controversy exists with respect to the utility of nebulized epinephrine in treating bronchiolitis. A meta-analysis of 14 studies concluded that there is not enough evidence to support the use of epinephrine for inpatients, but it does provide some clinical benefit over other bronchodilators and placebo for outpatients.\textsuperscript{147} Treatment does not decrease the rate of hospitalization, nor the length of hospital stay.\textsuperscript{148} One difficulty with the use of epinephrine in the ED is that it is not a treatment that can be continued at home. Thus, nebulized epinephrine should be considered for children with moderate to severe distress in whom beta-agonist therapy was not effective and who will likely require hospitalization. As with SABAs, nebulized epinephrine should be continued only for those patients who demonstrate a clinical benefit.

Studies on the use of nebulized anticholinergic agents (e.g., ipratropium bromide) have not been conclusive. While one study in the ED setting reported a decreased need for additional treatment for patients receiving an anticholinergic medication in addition to SABAs,\textsuperscript{149} a similarly designed ED study found no benefit.\textsuperscript{150} There is currently not sufficient evidence to recommend the use of anticholinergic agents for young children with wheezing and suspected bronchiolitis.\textsuperscript{151}

Many of the symptoms of bronchiolitis are a result of increased and thickened respiratory secretions. A great deal of literature supports the use of nebulized hypertonic saline in the treatment of cystic fibrosis, in which clearance of thickened secretions is vital.\textsuperscript{152-154} Although there is not yet enough literature to definitively recommend its use for bronchiolitis, one recent study suggests that nebulized hypertonic saline is a safe medication that reduces the length of stay for hospitalized children.\textsuperscript{135} Chest physiotherapy has also been examined as a means for clearing respiratory secretions. A meta-analysis of three randomized, controlled trials revealed no improvement in clinical score, length of stay, or oxygen requirement after chest physiotherapy.\textsuperscript{156}

Systemic corticosteroids are well established as being effective treatment for wheezing due to acute asthma. Despite reports that more than half of infants may be prescribed corticosteroids when diagnosed with bronchiolitis,\textsuperscript{131} well-designed controlled trials have demonstrated no benefit for their use in terms of rate of admission, clinical score, or any other outcome.\textsuperscript{138,157,158} Specifically, Corneli and colleagues conducted a double-blind, randomized trial comparing oral dexamethasone with placebo in 600 children with acute moderate-to-severe bronchiolitis. The investigators concluded that oral dexamethasone had no significant effect on the rate of hospitalization, respiratory status after 4 hours of observation, or later outcomes, such as length of inpatient stay, repeat medical visits, and adverse events. Inhaled corticosteroids also provide no positive effect on clinical course.\textsuperscript{159}

While infants with severe bronchiolitis requiring intensive care and mechanical ventilation frequently have concurrent or secondary bacterial infections,\textsuperscript{160} this is an uncommon complication for most children. Despite some reports that clarithromycin may hasten recovery in RSV bronchiolitis,\textsuperscript{161} there is no evidence for the routine use of antibiotics for bronchiolitis.

---

**Figure 167-2.** Emergency department management of bronchiolitis.
and they should be reserved for patients with true bacterial infections.\textsuperscript{138,162}

Ribavirin is a specific antiviral agent directed toward treatment of RSV infections. Several smaller studies suggest a small benefit with respect to duration of mechanical ventilation and length of stay in patients with severe disease.\textsuperscript{163} Its high cost and potential risks to caregivers, however, limit its role in routine management. Ribavirin may be indicated in selected cases of documented RSV bronchiolitis with severe respiratory compromise.\textsuperscript{138}

**Prophylaxis**

Though ED clinicians generally do not have a role in administering preventive medications, they should be aware of the options available to their patients. Palivizumab (Synagis) consists of monoclonal antibodies against RSV. While RSV-specific immune globulin is not effective in treating the acute disease process,\textsuperscript{164} palivizumab is quite effective in reducing hospitalization rates for RSV in certain high-risk populations.\textsuperscript{165–168} It is recommended for most children younger than 24 months with chronic lung disease, congenital heart disease, or prematurity and is administered as a monthly intramuscular injection during the high prevalence months.\textsuperscript{169}

**Disposition**

An essential component in the evaluation and management of bronchiolitis in the ED is the ability to predict the severity of its clinical course. Because it is a dynamic disease, evaluations at a single point in time may not be sufficient to fully estimate its severity; thus, serial examinations are necessary. A number of demographic and clinical features have been associated with a severe clinical course. These factors, which may mandate hospitalization, include age less than 3 months, gestational age less than 34 weeks, ill appearance, hypoxemia ($\text{SaO}_2 < 95\%$), tachypnea (>70 breaths/min), and significant atelectasis on CXR (if obtained).\textsuperscript{170} Most of the literature, however, focuses on inpatients. In addition to younger age and prematurity, a history of hemodynamically significant congenital heart disease, chronic lung disease, or an immunocompromised state have all been associated with higher morbidity and mortality among inpatients.\textsuperscript{138,171,172}

Ultimately, the ED clinician must assess more than just the child’s degree of respiratory distress. Patients for whom the respiratory symptoms negatively impact their ability to feed and maintain hydration warrant inpatient admission. Assessing the family’s ability to continue supportive measures at home and to seek further medical care if necessary is central to the disposition decision. In children for whom outpatient management is deemed appropriate, expedient follow-up (within 24 hours) with a primary care provider is essential. If SABA therapy provides a sustained clinical improvement in symptoms in the ED, it should be continued as part of home therapy. On the other hand, for the subset of infants who fail to respond to SABA therapy yet meet other criteria for discharge, outpatient treatment with SABAs is not warranted. As in all of pediatric medicine, anticipatory guidance must be provided. Parents should be instructed about the signs of worsening respiratory distress, including poor feeding, retractions, increased tachypnea, lethargy, or irritability; seeking immediate medical care is warranted should these signs occur.

**Summary**

Bronchiolitis is a common respiratory disease in infancy that accounts for many ED visits and hospitalizations. It is primarily a clinical diagnosis based on key history and physical examination findings. Serious complications, such as apnea, are rare and mostly occur in very young infants or those with underlying medical conditions. Treatment is largely supportive, and the use of nebulized SABAs may be helpful for a subset of patients. Ultimately, ED clinicians must understand the dynamic and variable nature of bronchiolitis and be able to effectively predict the severity of its clinical course.

Perspective

Background

Acute infections of the respiratory tract are among the most common infections of the human host. Although most of these infections involve the upper respiratory tract, physicians caring for children in the emergency department commonly encounter lower respiratory infections, most notably bronchiolitis and pneumonia. Bronchiolitis is primarily seen in children less than 2 years of age and is defined as wheezing and congestion due to a viral or bacterial lung infection. Pneumonia is an inflammation of the lung tissue and is most often due to an infection but occasionally may follow a noninfectious insult. Although the diagnosis of pneumonia may be suggested by clinical signs and symptoms, pneumonia is diagnosed by an abnormal chest radiograph showing pulmonary infiltrates. The clinical picture of pneumonia is variable and may range from a mild illness to life-threatening disease. Given the multiplicity of agents that can cause pneumonia and the limitations of diagnostic testing, determining a precise etiologic diagnosis may be difficult. Clinical, laboratory, and radiographic findings sometimes suggest a specific organism, but often the etiology remains unclear.

Epidemiology

Infection rates for pneumonia in children vary inversely with age, averaging 40 per 1000 in preschool-aged children and decreasing gradually to 7 per 1000 in 12- to 15-year-olds, with a male predominance of 2:1. Three fourths of all deaths from pneumonia result from bacterial infections.1

The causative organisms also vary with the age of the child. Because the organism is not definitively identified in most pneumonia cases, it is difficult to determine the true incidence of the specific etiologic agents.2 Overall, it has been estimated that viral agents cause 60 to 90% of pneumonias.3 Viral agents are more common in younger children. Bacteria predominate in neonates but are a less common causative agent in toddlers and older children. Outside of the neonatal period, the incidence of bacterial agents is stable throughout different age groups.3 Mixed viral and bacterial infections or concomitant bacterial infections may occur in one third of pneumonias.3,5 Chlamydia trachomatis is a unique cause of pneumonia in infants 3 to 19 weeks old. Bordetella pertussis classically occurs in children younger than 1 year but also occurs in older children and adolescents.6,7 Mycoplasma pneumoniae is one of the most common causes of pneumonia among children older than 5 years and may play a role in younger children.3,8 Chlamydia pneumoniae is more common in children older than 5 years but also may cause infection in younger children.3,9

Among bacteria, group B streptococci and gram-negative bacilli predominate in neonates. Ureaplasma urealyticum and Listeria monocytogenes may cause illness in infants younger than 3 months.3 Strepococcus pneumoniae is the leading bacterial cause of pneumonia in all age groups beyond the newborn period; Haemophilus influenzae and Staphylococcus aureus are less common etiologic agents, most often seen in the first years of life. The incidence of H. influenzae type B disease has decreased by 90% since the onset of immunization of infants and young children.10 The heptavalent pneumococcal conjugate vaccine, Prevnar (Lederle Laboratories/Wyeth-Ayerst Pharmaceuticals, Wayne, NJ), was licensed by the U.S. Food and Drug Administration in 2000 and is recommended as a primary series at 2, 4, and 6 months of age, with a fourth booster dose given at 12 to 15 months of age. Clinical trials suggested 85% protection against serotype-specific cases of bacteremic pneumonia.11 Studies have also shown a decrease in carriage rates of the serotypes included in the day care setting.12 Pneumococcal polysaccharide vaccines have been recommended for children older than 2 years at high risk for pneumococcal disease since 1985, but they are not immunogenic in younger patients. Pneumococcal vaccine has also been shown to provide some protection against viral pneumonia. One study found a 31% reduction in the incidence of pneumonia associated with seven respiratory viruses in hospitalized children. This may be because viral pneumonia in hospitalized children is often associated with concurrent pneumococcal infection.13 Other, less common bacterial agents include group A streptococci, Neisseria meningitidis, and anaerobic bacteria, the latter being particularly common in the setting of aspiration pneumonia. Unusual causes of pneumonia include Pseudomonas aeruginosa, Legionella pneumophila, Pneumocystis carinii, and rickettsial infections. The incidence of Mycobacterium tuberculosis is increasing in the United States, particularly in urban and low-income areas and among nonwhite racial/ethnic groups. Infants and adolescents are at highest risk in the United States.

Respiratory syncytial virus (RSV) and parainfluenza are the most common viral agents in infants younger than 1 year. Viruses that may be responsible for neonatal pneumonia include rubella, cytomegalovirus (CMV), and herpes simplex
virus. Other viral agents include influenza, adenovirus, rhinovirus, enterovirus, measles, varicella, and Epstein-Barr virus. The immunocompromised host is susceptible to all the aforementioned causes of pneumonia and mixed and opportunistic infections, including bacterial, viral (CMV, varicella), protozoan (P. carinii), and fungal disease.

**Principles of Disease**

**Pathophysiology**

The lung is protected from infection by a variety of local and systemic immune mechanisms. Passively acquired maternal antibodies are important in protection against *S. pneumoniae* and *H. influenzae* infections during the first few months of life. Children with altered protective mechanisms are at increased risk for developing pneumonia; this includes children with congenital anatomic abnormalities (cleft palate, tracheoesophageal fistulas, pulmonary sequestration, congenital cystic adenomatoid malformation), immune deficiencies, neurologic alterations that predispose to aspiration (coma, seizures, cerebral palsy, general anesthesia), and alterations in quality of secreted mucus (cystic fibrosis [CF]).

Bacterial pneumonia and mycoplasmal infections are transmitted most often person to person by droplet aspiration. Asymptomatic upper airway colonization commonly occurs in children and may spread infection to other children. Less commonly, bacterial pneumonia also may result from hematogenous spread from a distant focus or during primary bacteremia. Viral agents that cause pneumonia proliferate in the upper respiratory tract and spread contiguously to involve the lower respiratory tract. Viruses such as varicella, CMV, herpes simplex, Epstein-Barr, measles, and rubella also may infect the lung through hematogenous spread.

**Clinical Features**

**Symptoms and Signs**

**History.** Clinical symptoms and signs of pneumonia in pediatric patients vary with the age of the patient, specific pathogen, and severity of the disease. Infants younger than 3 months generally have respiratory symptoms, such as tachypnea, cough, retractions, and grunting, and nonlocalizing symptoms, including isolated fever or hypothermia, vomiting, poor feeding, irritability, and lethargy. Toddlers with *S. pneumoniae* may have nonspecific symptoms, such as high fever and lethargy, without respiratory symptoms. In general, with increasing age, signs and symptoms in children become more specific and are manifestations of generalized infection, lower respiratory tract disease, and associated extrapulmonary disease, although pneumonia in any child may have only a few or subtle manifestations. General symptoms related to the infection include fever and chills, headache, rigors, and malaise. Symptoms of lower respiratory tract disease may include cough and wheezing. Pleural irritation may cause chest, abdominal, or pleural tenderness or meninges. Vital signs including oxygen saturation also should be evaluated on arrival. Important findings include toxicity, level of alertness and interaction, color, and state of hydration and perfusion. Fever most often is present with bacterial pneumonia but may be low grade or absent in neonates and patients with nonbacterial disease. Cardiovascular parameters may indicate dehydration or, rarely, shock. Tachypnea, although not universal, is the most sensitive indicator of pneumonia and may be the only manifestation in a young child. The World Health Organization has published guidelines for the clinical diagnosis of pneumonia in developing countries and cites tachypnea and retractions as indicators of lower respiratory disease. Tachypnea is defined by the World Health Organization as a respiratory rate of greater than 50 breaths/min in infants younger than 1 year and greater than 40 breaths/min in children older than 1 year. Other manifestations of lower airway disease may include cough, wheezing, nasal flaring, retractions, grunting, and use of accessory muscles. The characteristics of the cough may aid the diagnosis; a staccato and paroxysmal cough in an infant may indicate pneumonia caused by *C. trachomatis* or *B. pertussis*. A hacking quality is often present with Mycoplasma infection. Auscultatory examination of an older child may reveal rales, wheezing, and diminished breath sounds, often with dullness to percussion and associated decreased fremitus. Although these findings may be present, in a younger child the clinical findings are much less consistent; rales may be masked by poor inspiratory effort or noisy upper airway sounds.

Pleural irritation may cause abdominal tenderness or meningismus, and pulmonary hyperinflation may cause downward displacement of the liver and spleen. Extrapulmonary findings may include rhinorrhea, pharyngitis, stridor, or exanthems with viral infections; conjunctivitis with chlamydial disease; pharyngitis and exanthems with mycoplasmal pneumonia; or extrapulmonary infections, such as soft tissue abscesses, otitis media, sinusitis, meningitis, and pericarditis, with bacterial pathogens.

**Specific Disorders**

**Bacterial Pneumonia**

**Perspective.** *S. pneumoniae* is one of the most common bacterial agents causing pneumonia in children. Children at increased risk for developing infection from *S. pneumoniae* are children with immune deficiency, chronic renal disease, or functional or anatomic asplenia, and Native Americans. *S. aureus* pneumonia, although less common, tends to cause a more severe pneumonia, with more than 70% of all cases occurring in the first year of life. Children with foreign body aspiration, immunosuppression, or skin infections may be at increased risk for *S. aureus* pneumonia. Progression of the disease is rapid, with empyema (90%), pneumatocoele (50%), pneumothorax (25%), and bacteremia are common complications (Fig. 168-1). Since the mid-1990s, community-acquired methicillin-resistant *S. aureus* has been identified as an agent that may cause pneumonia in children. In contrast to classically described methicillin-resistant *S. aureus*, which is typically broadly resistant and nosocomially acquired, this agent is resistant to fewer antibiotics.

Before widespread immunization, *H. influenzae* was the second most common bacterial cause of pneumonia. However,
its incidence has decreased by 90% since the onset of effective immunization. Although *H. influenzae* previously was considered a disease of younger children, most cases now occur in older children. Although often clinically indistinguishable from *S. pneumoniae*, *H. influenzae* pneumonia has a higher incidence of associated pleural effusions (25–75%) and bacteremia (75–95%). Other foci of infection are more common and include meningitis, epiglottitis, septic arthritis, pericarditis, soft tissue infection, and otitis media.

Although still uncommon, the incidence of group A streptococcal pneumonia may have increased since the 1980s. One study reported an increase in the incidence from 0.16 per 100,000 in 1992 to 0.35 per 100,000 in 1999 in Canada, whereas another study suggested stable rates since the 1980s. Group A streptococcal pneumonia may occur sporadically and may occur as a complication of varicella. It is typically a severe illness with abrupt onset and rapid progression to toxicity and a high fatality rate (30–60% fatality rate reported in a study of all ages).

**Clinical Features.** Bacterial pneumonia beyond the neonatal period generally has a sudden onset and fever is almost universal (often temperature >39°C). Patients may or may not have a cough and often appear relatively toxic with tachypnea disproportionate to the fever. Confined rales or wheezes and localized decreased or tubular breath sounds commonly occur in older children, although the physical examination in a younger child may be completely unrevealing.

**Diagnostic Considerations.** Patients with pneumococcal infections often have a preceding dramatic presentation with high white blood cell (WBC) counts with associated pleural effusion and bacteremia in 10 to 30% of children. Radiographic findings may show an alveolar infiltrate in a patchy or consolidated lobar (Fig. 168-2) or subsegmental distribution, although patients with bacterial pneumonia may have an interstitial infiltrate. Bilateral involvement, pleural effusion, pneumatocele, and pneumothorax may occur with more severe disease. Although the WBC count may be normal with bacterial pneumonia, leukocytosis often occurs, sometimes exceeding 20,000/mm³. Uncomplicated bacterial pneumonia often has a rapid response to institution of appropriate antibiotics; a stagnant or worsening clinical picture should prompt further investigation.

**Management.** Of particular concern is the emergence of resistance to penicillin and cephalosporins. At this time, it seems that presentation and outcome of otherwise healthy children with pneumonia secondary to resistant pneumococcus may not differ significantly from the outcome of children with pneumonia secondary to penicillin-sensitive pneumococcus. Pneumonia caused by *S. pneumoniae* may be complicated by empyema, pleural effusion, lung abscess, or necrotizing pneumonia. Since the 1990s, there seems to have been an increase in the incidence of such complications, with one study noting an increase from 22.6% in 1994 to 53% in 1999 in children hospitalized with pneumococcal pneumonia. It does not seem that this increased incidence is related to intermediate resistant organisms. It is unclear if highly resistant organisms play a role. High-dose amoxicillin is recommended for initial outpatient treatment of suspected pneumococcal pneumonia in children younger than 4 years; a standard dose may be used in older children who are immunocompetent (Table 168-1).

**Viral Pneumonia**

Viral pneumonia occurs more commonly in the winter and generally has a gradual onset over several days, often with associated cough, coryza, and low-grade fever. Tachypnea may be the only physical finding; however, retractions, rales, and wheezing are common, with grunting, cyanosis, lethargy, dehydration, and apnea apparent in more severely affected children. The diagnosis of viral pneumonia is often made clinically. Rapid antigen testing may be useful in the diagnosis of RSV or influenza A and B. Other viral agents may be diagnosed with culture of nasopharyngeal secretions. Although in the past the use of viral cultures was limited by the time required to grow viruses, improved culture techniques may yield results within 2 days and prove useful in a patient in whom cause needs to be established.

The WBC count is variable but tends to be less than 15,000/mm³ with lymphocyte predominance. Radiographic findings typically include hyperinflation and peribronchial thickening with diffuse increase in interstitial findings. Patchy areas of consolidation may be present, representing lobular atelectasis or alveolar pneumonia. Although lobar consolidation and small pleural effusions may occur in viral pneumonia, these findings are more consistent with a bacterial cause.

Most viral pneumonias resolve without specific therapy. Because of the likelihood of bacterial superinfection and the
**Mycoplasma Pneumonia**

Mycoplasma pneumonia accounts for 10 to 20% of all pneumonias and was thought to occur most commonly in 5- to 18-year-olds. It is now clear that it also may play a significant role in younger children but is still rare in infants less than 1 year old. Classically the onset is gradual and insidious, but some patients also may present with abrupt onset of symptoms similar to its bacterial counterpart. Prodromal symptoms include fever, headache, and malaise followed several days later by a nonproductive, hacking cough. Patients also may present with perussis-like illness. Other symptoms of infection may include hoarseness, sore throat, and chest pain; coryza is unusual. Children with mycoplasmal pneumonia generally appear nontoxic. Patients may have rales, with wheezing occurring less often. Pharyngitis, cervical lymphadenopathy, conjunctivitis, and otitis media may occur occasionally. Bullous myringitis, although rare, is believed to be indicative of *Mycoplasma*. Rash is present in 10% of patients and may be urticarial, erythema multiforme, maculopapular, or vesicular. The course may be complicated by pneumatocoele, pleural effusion, pneumothorax, or bronchiectasis. *Mycoplasma*, typically thought to be a benign and self-limited infection, has been shown to play a significant role in exacerbating asthma and may cause chronic pulmonary structural abnormalities.

Physical findings generally are less impressive than the radiographic picture; involvement is usually unilateral and in the lower lobes. The radiographic findings are protean, however, and may show lobar consolidation, scattered segmental infiltrates, or interstitial disease. Pleural effusions may occur but are uncommon. The WBC count is usually normal; the erythrocyte sedimentation rate tends to be elevated. Laboratory diagnosis is problematic. Although used in the past, bedside cold agglutination testing is a poor indication of infection, especially in patients younger than 12 years old, and is rarely used today. Infection often is diagnosed clinically and treated empirically. Diagnosis may be confirmed with acute and convalescent antibody titers; however, patients may take 4 to 6 weeks to seroconvert, and some patients may fail to mount an immune response. Culture is not routinely available; polymerase chain reaction diagnosis at this time is available only from research laboratories. Complications are varied but unusual and include hemolytic anemia, myopericarditis, neurologic disease (meningoencephalitis, Guillain-Barré syndrome, transverse myelitis, cranial neuropathy), arthritis, and rash.

**Chlamydial Pneumonia**

*Chlamydophila trachomatis* is a common sexually transmitted infection, causing cervical infection in 2 to 30% of pregnant women. It can be transmitted from the genital tract of infected mothers to their newborn infants, resulting in conjunctivitis in 22 to 44% and pneumonia in 5 to 20%. An infant with pneumonia caused by *C. trachomatis* presents at 3 to 19 weeks of age after colonization with the organism at birth. The illness usually
begins with nasal congestion followed by cough. In half of the cases, conjunctivitis precedes the onset of respiratory symptoms. The infant is often afibrile, alert, and tachypneic, with a repetitive staccato cough. The cough may interfere with feeding or sleeping. It can resemble the paroxysms of pertussis and occasionally precipitates episodes of alarming respiratory distress. Mild retractions and diffuse inspiratory crepitant rales are noted on chest examination, with expiratory wheezing usually absent or minimal. Middle ear abnormalities are present in half of the cases.

The radiograph usually shows hyperinflation with bilateral and symmetrical diffuse interstitial infiltrates (Fig. 168-3). The total WBC count is usually normal but often with an eosinophilia of more than 400/mm³. Definitive diagnosis is made by isolating the organism in the tissue culture; diagnostic tests based on polymerase chain reaction are more sensitive than fluorescent antibody stain or tissue culture but may not be as specific. Although often a mild illness, chlamydial pneumonia may be complicated by apnea and hypoxemia. Treatment with erythromycin may shorten the course; however, the disease tends to be protracted with cough and tachypnea often requiring weeks to clear.

*Chlamydia pneumoniae* is a species of *Chlamydia* that is antigenically, genetically, and morphologically distinct from other *Chlamydia* species. *C. pneumoniae* infection is readily transmitted from person to person. *C. pneumoniae* may play a role in respiratory tract infections in infants and young children and may cause mild illness or asymptomatic infection in children and adults. As with *Mycoplasma*, *C. pneumoniae* may play a much greater role in pediatric pneumonia than previously thought. It also commonly may be present as a mixed bacterial infection. *C. pneumoniae* has been reported to cause sore throat, fever, headache, pertussis-like cough, pneumonia, and influenza-like illness. Outbreaks have been reported in schools, day care centers, military camps, adolescents, and families. Infected with *C. pneumoniae* can trigger acute episodes of wheezing in children with asthma.  

### Pertussis

Pertussis, or whooping cough, is a respiratory tract infection seen most commonly in infants younger than 6 months (38% of cases are in children <6 months old, and 71% of cases are in children <5 years old). The incidence of pertussis increased in the 1980s and 1990s, especially in adolescents and adults, despite high immunization rates.

The disease is characterized by three clinical stages: catarrhal stage, paroxysmal stage, and convalescent stage. In infants, the disease begins with mild upper respiratory tract symptoms and cough; this catarrhal stage usually lasts 1 to 2 weeks. The disease progresses to severe paroxysms of a staccato cough followed by post-tussive emesis and may be accompanied by periods of cyanosis and apnea in infants younger than 6 months. Classic whoop is rare, occurring only in 6% of patients, and is generally seen in children older than 2 to 3 years. Fever is often absent, and between paroxysms the examination is remarkably normal. Paroxysms sometimes may be induced on physical examination by gagging the patient. The paroxysmal stage lasts 2 to 4 weeks and is followed by a convalescent stage during which symptoms gradually wane. The duration of the illness in complicated cases may be 6 to 10 weeks.

Immunization is only 80% effective in providing immunity after three doses: Pertussis still must be considered in an immunized infant, although the illness may be mild. The WBC count is usually elevated, exceeding 15,000/mm³ and occasionally 40,000/mm³, with a marked lymphocytosis, although this finding may not be present in infants younger than 3 to 6 months old. The chest radiograph may show a “shaggy” right heart border or have clear lung fields. The organism is most easily recovered in the catarrhal or early paroxysmal stages and is rarely found after the fourth week of illness. *B. pertussis* can be cultured from nasopharyngeal secretions. Cultures may be negative during the first week or after the fourth week of illness in immunized patients or patients treated with antibiotics. Direct fluorescent antibody staining may be used, but this test has low specificity and variable sensitivity. Diagnosis made by direct fluorescent antibody should be confirmed by culture.

Polymerase chain reaction may be more sensitive and specific, but availability is variable. Pertussis is a particularly severe disease in the first year of life; complications are common and include apneic episodes, seizures, secondary bacterial pneumonia, encephalopathy, and death. Pertussis has been increasing in incidence among immunized children and young adults who have waning immunity. Adults are believed to be a significant source for the disease within the community. The illness in these patients does not follow the classic stages as described here. These patients have a mild but prolonged course. A dry cough is the predominant symptom, often lasting 3 weeks or more. All children younger than 6 months with presumed pertussis should be observed in the hospital because of the risk of apnea for monitoring and supportive care and should be treated with erythromycin. Other macrolides and trimethoprim-sulfamethoxazole are possible alternatives. Antimicrobials have no effect on the disease progression after the paroxysmal stage is established but may be beneficial because they limit the spread of organism.

### Aspiration Pneumonia

Aspiration pneumonia may be due to mechanical, chemical, or bacterial causes. Bacterial aspiration occurs in children with anatomic abnormalities and central nervous system disturbances that impair normal swallowing or protective airway reflexes. Pulmonary damage results from chemical (e.g., stomach acid) and bacterial (gastrointestinal and upper respiratory organs) insults. Within several hours of the aspiration, the child may have the onset of cough, tachypnea, and fever. Physical examination commonly reveals rales and wheezing with cyanosis as the disease progresses. Radiographic findings include localized (right middle lobe, right lower lobe) and diffuse infiltrates, which are often bilateral.
Pneumonia in an Immunocompromised Host

Children with chronic disease and congenital, acquired, and iatrogenic immune deficiencies are susceptible to the aforementioned respiratory pathogens and to a multitude of opportunistic organisms, including *P. carinii*, CMV, and fungi. Presenting symptoms may be similar to normal hosts; however, the course tends to be more rapid, severe, and fulminant. Rigorous attempts to identify a pathogen are warranted, and patients should be hospitalized for this investigation and to await the results of cultures for monitoring, supportive therapy, and treatment with intravenous antibiotics active against a broad spectrum of organisms. If the patient fails to improve after initial therapy, obtaining tissue for diagnosis of potentially treatable organisms is necessary.

Diagnostic Strategies

Not every child suspected to have pneumonia requires laboratory or radiographic evaluation. A well-appearing child with cough and rales may be diagnosed clinically and treated as an outpatient. A child who appears ill or in whom the diagnosis is unclear requires further evaluation. Young children with high fever and leukocytosis may have an occult pneumonia. A chest radiograph should be considered in these patients.

Laboratory Studies

Any child with pneumonia is at risk for hypoxemia and should have pulse oximetry to determine oxygen saturation. An arterial blood gas study is not needed in most patients but may be considered in a child with severe respiratory distress; it may be useful in following the effectiveness of respiratory status or ventilation. Serum electrolytes, blood urea nitrogen, and creatinine are useful in assessing the degree of dehydration and guiding fluid management when clinically relevant.

Further laboratory studies are obtained only as warranted to help identify the disease process and potential complications. The leukocyte count may be useful in differentiating causes of pneumonia; peripheral WBC counts greater than 15,000/mm³, with predominance of mature and immature granulocytes, suggest bacterial infection, with pneumococcal pneumonia typically producing the highest WBC counts. Marked leukocytosis and toxic granulation of WBCs also may help identify a child at risk for bacteremia and its potential complications. Normal to elevated WBC counts with lymphocytosis may be seen in viral infections, and eosinophilia suggests chlamydial disease. Increased WBC counts with extreme lymphocytosis typically are associated with pertussis, but this hematologic finding may be absent in infants younger than 6 months. Blood cultures may grow pathogens in only 1 to 10% of cases of bacterial pneumonia. Unfortunately, the contamination rate at most hospitals for cultures is in this range as well. In a well-appearing child with an uncomplicated pneumonia, blood culture is unlikely to be helpful. When a blood culture is positive, however, it identifies the specific pathogen and should be considered in an ill patient in whom hospitalization with bacterial pneumonia is likely. Sputum cultures may be useful in adolescents but are technically very difficult and not useful in younger children.

Patients with pleural effusions should have lateral decubitus radiographs to assess effusion size and loculation. Computed tomography scan is useful to provide greater detail of effusions and lung abnormalities in critically ill children with complicated pneumonia. Routine computed tomography to establish the diagnosis is not recommended. Patients with significant effusions should have thoracentesis for diagnostic and therapeutic purposes. Although most suggestive of bacterial infection, parapneumonic effusions also occur with mycoplasmal and occasionally with viral infections. The fluid should be sent for Gram stain and culture (anaerobic and aerobic bacterial) and cell count and differential, total protein, pH, and glucose determinations. Interpretation of pleural fluid in children follows adult guidelines (see Chapter 75). Cultures for rare pathogens may be considered if initial assessment is not diagnostic. Bronchoscopy with bronchoalveolar lavage may be useful in a severely ill child.

Nasopharyngeal viral cultures, antigen detection for specific viral or bacterial agents, and serum antibodies for specific agents may be helpful in determining certain etiologic agents. Although most pediatric patients with tuberculosis do not have pulmonary symptoms, skin testing for tuberculosis should be considered for patients with lobar pneumonia, pulmonary effusions, or hilar adenopathy, especially in immunocompromised children or children who have recently immigrated from less developed countries. Acid-fast bacilli often may be shown on an early morning gastric aspirate.

Sputum specimens generally are not helpful in a child younger than 8 years because of contamination by organisms of the upper respiratory tract.

Bacterial cultures of upper respiratory secretions are of no value and usually grow either normal flora or organisms that reflect only colonization. Although transtracheal sampling and direct aspiration from the lung may permit a more precise diagnosis, the invasiveness of these tests limits their usefulness. Evaluation of potential additional infectious foci should be guided clinically with particular attention to the meninges, pericardium, epiglottis, soft tissue, and joints to identify the offending pathogen and to delineate the disease process fully.

Radiology

A chest radiograph may be obtained to confirm or rule out an infiltrate. Rarely, a dehydrated child with pneumonia may have a normal study, and once they are rehydrated, the infiltrate becomes readily apparent. The radiograph also may provide clues as to the underlying disease process. Although great variability exists, bacterial pathogens classically produce alveolar infiltrates in a lobar distribution but may produce diffuse interstitial infiltrates. Viral and chlamydial infections tend to appear as diffuse interstitial infiltrates, commonly with hyperinflation and atelectasis. Chest radiographs also identify multilobar disease, pleural effusions, pneumatoceles, and pneumothorax (Fig. 168-4). Hilar adenopathy may indicate tuberculosis or malignancy.

Children without comorbid conditions, who are without fever, unilateral wheezing, or tachypnea, are unlikely to have pneumonia and a chest radiograph is unnecessary. Further, a Cochrane review demonstrated that for non-ill-appearing children with less than 14 days of symptoms and clinical signs of pneumonia, chest radiography does not reduce subsequent hospitalization rate nor duration of symptoms. Routine chest radiography is not beneficial in ambulatory children over 2 months with acute lower respiratory infections.

Differential Considerations

The major conditions to be differentiated in children with pneumonia include bacterial pneumonias amenable to conventional antibiotics, viral disease, other unusual infectious causes (mycobacterial, protozoal, fungal), and noninfectious pathologic conditions (Box 168-1). Certain features help differentiate the common infectious causes (Table 168-2).
infection from children with nonbacterial pneumonia. Because of limitations of reliably detecting bacterial pneumonia by culture technique, one should presume a bacterial cause in a child with a temperature greater than 39°C, clinical toxicity, lobar infiltrate, or pleural effusions. Although it is often difficult to make a precise etiologic diagnosis, consideration of host factors, epidemiology, and the clinical picture with judicious use of laboratory tests generally points the clinician toward the likely diagnosis and allows for effective patient management.

Complications

Several complications of pneumonia result from local and systemic effects of the infection. Pleural effusions or empyemas accumulate most often with bacterial pathogens (notably *S. pneumoniae*, *H. influenzae*, and *S. aureus*) but are occasionally associated with mycoplasmal, viral, and tuberculous pneumonia. An increase in the occurrence of such complications seemed to have occurred in the 1990s for reasons unknown. Similarly, lung abscess, pneumonia, and pneumothorax are local complications primarily seen with bacterial disease, particularly with *S. aureus*. Extensive pulmonary involvement of any cause may lead occasionally to hypoxia and progressive respiratory failure with multiple organ failure. Apnea without other symptoms is seen most often in viral, chlamydial, and pertussis infections in infants younger than 3 months. The most common systemic complication of pneumonia is dehydration, which occurs as a result of decreased intake from malaise and excessive respiratory effort and increased losses of fluid caused by vomiting, fever, and tachypnea. Another systemic complication of bacterial disease is the development of additional infectious foci resulting from bacteremia (e.g., meningitis, epiglottitis, pericarditis, septic arthritis, and soft tissue infections). Mycoplasmal pneumonia rarely is associated with meningitis, encephalitis, arthritis, and hemolytic anemia.

Management and Disposition

Infants Less Than 2 Months of Age

Treatment of pneumonia in a pediatric patient consists of appropriate antimicrobial use and supportive therapy (see Table 168-1). Because of the difficulty in identifying an etiologic agent, antibiotic choice is generally empirical. The three most important factors in directing management are the patient’s age, likely pathogen, and degree of illness. An infant younger than 2 months with pneumonia should be admitted to the hospital. This age group is immunologically immature, and signs of sepsis may be subtle. Blood, urine, and cerebrospinal fluid cultures generally are indicated before initiation of antibiotics.

Infants 2 to 3 Months of Age

In an infant 2 to 3 months old, blood and urine cultures are appropriate. The decision to perform a lumbar puncture depends on clinical suspicion of central nervous system infection. Ampicillin plus an aminoglycoside or ampicillin and a third-generation cephalosporin would be appropriate initial antibiotic choices for an infant younger than 1 month (although ceftriaxone is contraindicated in infants <1 month old). Amoxicillin and a third-generation cephalosporin are reasonable for an infant 1 to 3 months old. If *C. trachomatis* or *B. pertussis* is suspected, the infant also should be treated with erythromycin after appropriate diagnostic samples have been obtained; other macrolides or sulfonamides (trimethoprim-sulfamethoxazole) detailed previously, each disease entity has certain classic historical, clinical, and laboratory findings. At the extremes of presentation, these diseases can be distinguished easily; however, the broad spectrum of illness for each process may make accurate diagnosis in an individual patient difficult. No specific feature reliably differentiates patients with bacterial pneumonia.

**Infants and Children Greater Than 3 Months of Age**

An older child with pneumonia should be categorized into likely bacterial, viral, or mycoplasmal disease if possible. Because no single pathognomonic test exists to differentiate bacterial from viral infection, the physician must base the presumptive etiologic diagnosis on clinical, radiographic, and laboratory findings. Although the categorization is not always clear, a toxic child with high fever, lobar consolidation, and leukocytosis is likely to have a bacterial process, whereas a child with a disease of gradual onset, low-grade fever, and interstitial infiltrate with air trapping is more likely to have a viral process.

If a viral agent is suspected and the child is not ill, antibiotics may be withheld. Uncomplicated bacterial pneumonia in immunocompetent children is safe to treat as an outpatient disease. A well-appearing infant or preschool-aged child with isolated pneumonia may be treated with oral antibiotics on an outpatient basis. In an infant beyond the neonatal period or a preschool-aged child, amoxicillin and amoxicillin-clavulanic acid are considered appropriate first-line agents. Cefuroxime axetil or high-dose amoxicillin (80–100 mg/kg/day) may be used when resistant *S. pneumoniae* is suspected. Azithromycin or clarithromycin also are considered appropriate first-line oral agents in this age group by some researchers. One study of the treatment of pediatric community-acquired pneumonia showed no difference in clinical cure rate when azithromycin, erythromycin estolate, and amoxicillin-clavulanic acid were compared.40 A macrolide is the first-line antibiotic choice in a school-aged child or adolescent in whom *M. pneumoniae* and *C. pneumoniae* are more common. Every child with bacterial pneumonia treated as an outpatient should be reevaluated within 24 to 48 hours. Patients who are not afebrile, clinically improved, and well hydrated should be evaluated at this time for possible admission to the hospital for parenteral antibiotic therapy. For patients in whom signs of bacteremia are present, a single dose of intramuscular ceftriaxone followed by outpatient oral therapy is recommended. In these cases, close follow-up monitoring is crucial.

For a patient who is admitted to the hospital, intravenous therapy with cefuroxime, cefotaxime, or ceftriaxone is appropriate. Addition of a macrolide should be considered if *M. pneumoniae* is a possible etiologic agent. Vancomycin should be added if methicillin-resistant *S. aureus* is suspected. If an organism has been identified, an antibiotic with a more specific spectrum might be indicated.

Since the 1980s, *S. pneumoniae* has been developing increasing resistance to penicillin and other antibiotics; in general, this has not been clinically relevant because higher doses overcome the relative resistance. Clinical outcomes with intermediate resistance levels seem to be unchanged. These patients...
Cillin-resistant have been changing. The spectrum of antimicrobial sensitivity patterns of etiologic organisms require parenteral antibiotics, support, and hospitalization.

Over the past several years, the patterns of etiologic agents. Common pathogens may be treated as an outpatient disease in nontoxic patients; infants or if the illness is not the child's first episode of pneumonia, a chest radiograph should be obtained to ensure complete resolution, or if the illness is not the child's first episode of pneumonia, a chest radiograph should be performed 6 to 8 weeks after diagnosis.

A trial of bronchodilators may be worthwhile (aerosolized beta2-adrenergic agent) even in the absence of wheezing and always should be considered in a patient with respiratory distress. Although this treatment is not always successful, if the child responds with diminished wheezing, improved aeration, or reduced work of breathing, one may continue with nebulized bronchodilators.

Children with neurologic or anatomic abnormalities who aspirate oral or gastric contents are susceptible to pneumonia predominantly from anaerobes. Penicillin and clindamycin are appropriate first-line antibiotic choices. In seriously ill patients, agents such as chloramphenicol, metronidazole, and cefoxitin may be more useful. Nosocomial infections should be treated with antibiotics also active against aerobes and gram-negative bacilli. Children with significant aspiration should be admitted to the hospital, and supportive therapy should include hydration, supplemental oxygen, oropharyngeal suctioning, and intubation of the trachea if airway reflexes are impaired or respiratory failure is manifest.

Long-term management of a child with pneumonia should include a clinical reevaluation 2 to 3 weeks after diagnosis. If the child had a prompt response to therapy and is entirely well at follow-up evaluation with a normal physical examination, a repeat radiograph is unnecessary. If the child has undergone a complicated disease course (e.g., pleural effusion), has residual symptoms, or manifests any abnormality on examination, or if the illness is not the child's first episode of pneumonia, a chest radiograph should be performed to ensure complete resolution of the disease. The follow-up radiograph should be performed 6 to 8 weeks after diagnosis.

In managing a child with pneumonia, it is essential to consider the age and clinical presentation of the child in delineating specific etiologic agents. Common pathogens may be treated as an outpatient disease in nontoxic patients; infants and children who exhibit some respiratory compromise may require parenteral antibiotics, support, and hospitalization. Over the past several years, the patterns of etiologic organisms have been changing. The spectrum of antimicrobial sensitivities also has changed, particularly with the emergence of penicillin-resistant S. pneumoniae. Repeat chest radiographs are indicated in children who fail a course of therapy; immunocompetent patients that respond to therapy may be followed clinically and a repeat chest radiograph is not necessary to document cure.

OTHER RESPIRATORY EMERGENCIES

Cystic Fibrosis

Perspective

Cystic fibrosis is an autosomal-recessive disease caused by a mutation in the CF transmembrane conductance regulator (CFTR) gene. In whites, approximately 1 in 25 is a carrier, and the disease has an incidence of 1 in 2500 births. The disease also is present (in decreasing incidence) in Hispanics, Native Americans, African Americans, and Asians. Progressive lung disease and infection account for most of the morbidity and nearly all of the mortality in CF. Defects in chloride transport across the airway epithelium result in reduced ciliary clearance of thickened mucus, decreased antimicrobial effect of the airway surface, increased bacterial adherence, and innate secretion of inflammatory cytokines. All of these factors result in a unique sensitivity to bacterial infection of the airways.

Diagnostic Strategies

Chest radiograph findings of CF include emphysema, peribronchial thickening, bronchiectasis, and focal infiltration, which may be linear or nodular in nature (Fig. 168-5). Crucial to the effective treatment of pulmonary infections in CF patients is the identification of pathogens involved, usually through sputum culture. Early childhood pneumonias in patients with CF are predominantly caused by S. aureus and H. influenzae.

Management

With the emergence of methicillin-resistant S. aureus, careful attention should be paid to antibiotic coverage. Patients on antistaphylococcal prophylaxis may be at increased risk for pseudomonal infections. There is emerging evidence that CF patients also are at increased risk for hospitalization by nonbacterial pathogens.

By 18 years of age, 80% of patients are colonized with P. aeruginosa. When colonization is established, it is generally considered permanent. Acute infective exacerbations generally are managed by oral and intravenous antimicrobial drugs, typically a penicillin (e.g., ticarcillin or piperacillin) or ceftazidime combined with an aminoglycoside for purposes of synergy. If a patient's previous sputum culture is available, care should be taken to ensure coverage of the last known bacterial pathogens. Resistant strains may benefit from imipenem or meropenem. Patients routinely are hospitalized for 10 to 14 days for the course of therapy.

Burkholderia cepacia, a significant pathogen in CF patients, has been associated with an accelerated decline in clinical status and increased mortality. Generally, antimicrobial coverage is similar to that for Pseudomonas. Resistance is common, however, and the existence of differing colonization and resistance patterns of patients with CF necessitates respiratory isolation from other susceptible individuals.

Clearance of thick mucoid secretions is vital for treatment. Patients may respond favorably to bronchodilator therapy and to mucolytics, such as inhaled N-acetyl cysteine, in the acute setting. Chest physiotherapy often is provided by a.
A B

high-frequency oscillator device. A flutter valve or a positive expiratory pressure mask also may be of assistance for improved mucoid clearance. Short-term control of inflammation may be obtained by inhaled corticosteroids.59

**Chronic Lung Disease**

Chronic lung disease (CLD) of infancy, also called *bronchopulmonary dysplasia*, is extremely common in premature infants and affects 40% of children with a birth weight of less than 1000 g.60 The severity of disease is related to several factors, including degree of prematurity, use of peripartum steroids, damage incurred by ventilation in the neonatal period, and nutritional status.61 Infants with CLD have greatly increased rates of hospitalization because of respiratory illness in the first year of life, approaching 65% in infants born weighing less than 1000 g.62

Immunizations are vital to the prevention of pneumonia in patients with CLD. All infants 6 to 23 months old should receive the influenza vaccine during the appropriate season. The heptavalent pneumococcal vaccine (Prevnar) and *H. influenzae* type B vaccine are especially vital for prevention of bacterial pneumonia.63 In addition, monthly prophylaxis against RSV is administered to carefully selected patients with the monoclonal immunoglobulin palivizumab, which reduces the incidence of RSV disease and risk of subsequent hospitalization.13,64

Patients with CLD have increased airway resistance, decreased lung compliance, and obstructive lung disease. Pneumonia in patients with CLD may be complicated by a reactive airway component. Radiographs show marked hyperinflation and infiltrates if complicated by pneumonia (Fig. 168-6). Inhaled bronchodilators may be efficacious, although these medications may worsen air exchange in patients with concomitant airway malacia. Hypoxia and hypercarbia are common, despite an increased respiratory effort. Patients with severe CLD may be receiving long-term diuretic therapy to improve lung mechanics; care should be taken not to confuse pneumonia with cor pulmonale, which is especially prevalent in younger infants with chronic supplemental oxygen requirements.60
It may be difficult to determine the etiologic agent for pneumonia by clinical presentation, radiographic findings, or laboratory studies. Mixed infections occur commonly.

Infants and younger children with pneumonia may have subtle or nonspecific signs and symptoms on presentation.

Pertussis should be considered in a young infant with a lower respiratory tract infection, staccato cough, or episodes of cyanosis.

*M. pneumoniae* and *C. pneumoniae* may play a role in pneumonia in a younger child.

In patients with CF, defects in chloride transport across the airway epithelium result in reduced ciliary clearance of thickened mucus, which results in increased likelihood for pneumonia, especially those caused by *P. aeruginosa*.

CF may respond favorably to bronchodilator therapy and to mucolytics, such as inhaled N-acetyl cysteine.

Patients with CLD have increased airway resistance, decreased lung compliance, and obstructive lung disease; reactive airway disease and pneumonia are common in these patients.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
Pediatric cardiac disease has typically been divided into congenital and acquired disorders, with a further subdivision of the congenital heart disorders into cyanotic and acyanotic lesions. From a purely clinical standpoint, however, children with cardiac disorders present to the emergency department in one of two scenarios. In the first scenario, the child has signs and symptoms that may represent an exacerbation or complication of an already known underlying cardiac disorder. In cases with a known underlying cardiac disorder, early consultation with the child’s cardiologist, along with comparisons of the child’s previous and most recent diagnostic cardiac studies such as chest radiographs, electrocardiograms (ECGs), and echocardiograms, would also be extremely useful in the evaluation and management phases.

The second scenario represents more of a challenge to the emergency physician: the child with an undiagnosed congenital or acquired cardiac disorder who presents to the emergency department with nonspecific or concerning signs and symptoms (Box 169-1). This chapter focuses on some of the more common and life-threatening cardiac disorders in infants and children who present to the emergency department, with an emphasis on rapid evaluation, stabilization, and management of these disorders.

Fetal and Neonatal Circulation

Some of the key features of the fetal circulation that differ from that of a child are the presence of the ductus venosus, ductus arteriosus, and a patent foramen ovale. During fetal development, oxygenation of the fetal circulation bypasses the fetal lungs and is accomplished via the placenta. Blood that is oxygenated by the placenta flows to the fetus via the umbilical vein, bypasses the fetal liver via the ductus venosus, and returns to the fetal heart via the inferior vena cava. Blood returning from the inferior vena cava then enters the right atrium and is preferentially shunted across to the left atrium via the patent foramen ovale (Fig. 169-1). The blood in the left atrium is then pumped out of the aorta via the left ventricle. The oxygenated blood that is ejected through the ascending aorta is preferentially directed to the fetal coronary and cerebral circulations.

Deoxygenated blood that returns to the right atrium via the superior vena cava crosses the tricuspid valve and is pumped into the fetal pulmonary artery via the right ventricle. Since the fetal pulmonary vascular resistance (PVR) is higher than the fetal systemic vascular resistance (SVR), this deoxygenated blood bypasses the nonoxygenated fetal lungs via the patent ductus arteriosus (see Fig. 169-1). The poorly oxygenated blood enters the aorta via the patent ductus arteriosus and then mixes with the well-oxygenated blood in the descending aorta. The mixed blood in the descending aorta then returns to the placenta for oxygenation via the two umbilical arteries.

Once the infant is delivered and the umbilical cord is cut, expansion and aeration of the lungs causes a decrease in PVR, with a concomitant increase in pulmonary blood flow. Increased oxygenation causes a physiologic closure of the umbilical arteries, umbilical vein, ductus venosus, and ductus arteriosus. An increase in the pulmonary blood flow to the infant’s left atrium also promotes closure of the foramen ovale. Complete anatomic closure of the foramen ovale does not occur until about 3 months of age. Although the ductus arteriosus functionally closes at about 10 to 15 hours of life, complete anatomic closure does not occur until about 2 to 3 weeks of life.

In the absence of any congenital cardiac defects, these transitional circulatory changes pose no physiologic problems to the infant. However, closure of the ductus arteriosus can pose life-threatening complications in neonates with specific congenital cardiac defects that are dependent on the patency of the ductus arteriosus for survival.

Pathophysiology of Cardiovascular Compensatory Responses

There are two fundamental and clinically useful physiologic formulas to keep in mind during the clinical assessment and management of cardiac disorders:

\[
\text{Cardiac Output} = (\text{Stroke Volume}) \times (\text{Heart Rate})
\]

\[
\text{Blood Pressure} = (\text{Cardiac Output}) \times (\text{SVR})
\]

The young myocardium is inefficient and unable to increase its contractility in response to demand. When more cardiac output is needed, infants and children respond with an increase in heart rate. Therefore, bradycardia in infants and young children is an ominous sign that connotes a severely compromised cardiac output. Children develop the adult capacity to increase their stroke volume to improve overall cardiac output by 8 to 10 years of age.
Based on the first physiologic formula, as stroke volume decreases, a compensatory increase in the heart rate will be necessary to preserve a normal cardiac output. A decrease in stroke volume can be produced by a weak “pump,” decreased volume in the circulation, or both. The most common cause of decreased stroke volume in children is hypovolemia due to dehydration. Other causes of decreased stroke volume in children may be responsible (Box 169-2). Thus, tachycardia is the first compensatory cardiovascular response when the stroke volume is decreased. If tachycardia alone is not enough to maintain a normal cardiac output, the next compensatory physiologic mechanism to preserve perfusion is an increase in the SVR. This increase in SVR is exhibited as an increase in the diastolic blood pressure, which in turn accounts for a narrowed pulse pressure. The clinical examination of the extremities of a child with an increased SVR includes pallor, mottling, cool skin, a delayed capillary refill time (>2 seconds), and weak or thready distal pulses.

**Pathophysiology of Cyanosis**

**Perspective**

Cyanosis is a clinical sign caused by the presence of deoxygenated blood in the capillary beds, most readily observed in the mucous membranes, conjunctiva, nail beds, and skin. The presence of cyanosis usually means that there are at least 4 to 5 g/dL of deoxyhemoglobin in the blood, which correlates to an oxygen saturation of about 80 to 85%. Pathophysiologically, central cyanosis results from a decrease in pulmonary ventilation/oxygenation, a decrease in pulmonary perfusion, shunting of deoxygenated blood directly into the systemic circulation, or the presence of abnormal hemoglobin. Cyanosis in the neonate can be due to a variety of cardiac, pulmonary, or hematologic causes. Cardiac causes of cyanosis include congenital lesions with right-to-left shunts as well as cardiac lesions with decreased or increased pulmonary blood flow. Common pulmonary causes of cyanosis include bronchiolitis, pneumonia, and pulmonary edema. Methemoglobinemia can be one of the hematologic causes of cyanosis.

**Clinical Features of Cyanosis**

The region of the body that is cyanotic can provide important clinical clues as to the cause of the cyanosis. Central cyanosis involves the lips, tongue, and mucous membranes, whereas peripheral cyanosis (acrocyanosis) involves the hands and feet. Acrocyanosis is a common phenomenon in neonates caused by

**Box 169-1**

**Figure 169-1.** Normal intracardiac fetal circulation: Physiologic shunting through the patent foramen ovale (FO) and the patent ductus arteriosus (DA). Oxygenated blood from the placenta (red arrows) reaches the right atrium (RA) via the inferior vena cava (IVC). This well-oxygenated blood is preferentially shunted from the RA across to the left atrium (LA) through the FO and is then ejected out the left ventricle (LV) to the ascending aorta (AO). Deoxygenated blood (blue arrows) returning from the superior vena cava (SVC) preferentially travels from the RA into the right ventricle (RV) and then out through the main pulmonary artery (PA). Because of the high pulmonary vascular resistance in the fetal lungs, this deoxygenated blood bypasses lungs and enters the descending aorta via the DA. Thus, the areas of the fetal body that are perfused by arteries proximal to the DA receive well-oxygenated blood, whereas those areas of the body that are perfused by arteries distal to the DA receive blood with a mixed oxygenation. LPA, left pulmonary artery; RPA, right pulmonary artery.

Cyanosis due to severe pulmonary disease (e.g., severe pneumonia, tension pneumothorax, acute chest syndrome of sickle cell disease) may not show significant improvement with supplemental oxygen, but these children will also typically exhibit severe respiratory distress along with clinical cyanosis.

CLINICAL FEATURES AND DIAGNOSTIC STRATEGIES: THE CARDIAC EVALUATION

The key elements that should be elicited in the history of a child with a known underlying cardiac disorder are listed in Box 169-3. Early consultation with the child’s cardiologist or cardiac surgeon is extremely useful. The other important points to cover in the history of a child with a potential or suspected cardiac disorder are addressed in the subsequent sections of this chapter.

In addition to a well-focused history and physical examination, a chest radiograph and an ECG should be obtained on any child with a known or suspected cardiac disorder. Other ancillary studies that can also be useful include an arterial blood gas analysis, hemoglobin/hematocrit levels, digoxin levels in those patients on daily digoxin, serum electrolytes in the child who appears “comfortably blue.” Another important clinical clue to the cause of central cyanosis is that cyanosis of cardiac origin usually worsens with crying, whereas cyanosis due to a pulmonary cause may improve when the infant cries. Cyanotic congenital heart defects with right-to-left shunting will demonstrate a minimal improvement with supplemental oxygen, whereas cyanosis of a purely pulmonary origin typically exhibits a significant improvement with supplemental oxygen (Table 169-1).

History

The presence of certain maternal medical conditions has been associated with a higher incidence of cardiac disorders. For example, congenital heart blocks have been associated with maternal systemic lupus erythematosus and other collagen vascular disorders; infants of diabetic mothers have a higher incidence of cardiomyopathy.

Infants with an underlying congenital heart disorder may exhibit diaphoresis during feeds and poor weight gain secondary to congestive heart failure (CHF). The cause of the infant’s hypoxia—cardiac or pulmonary—may be ascertained by the age at onset and the events surrounding a change in color. For example, an infant who sweats during feeding may exhibit a splanchnic steal from anomalous coronary arteries, causing transient ischemia, pain, color change, and diaphoresis that resolve after eating.1 A child with an undiagnosed congenital heart defect may take longer to feed, frequently pausing to catch his or her breath, with subsequent poor weight gain and gradually increased work of breathing due to developing CHF and pulmonary edema. Respiratory tract infections are common during childhood and may cause an acute deterioration in a child with an underlying cardiac disorder. In turn, children with congenital heart disease (CHD) with large left-to-right shunts and increased pulmonary blood flow tend to have a higher incidence of lower respiratory tract infections. Acute respiratory distress in these patients may be from a combination of pulmonary and cardiac factors (e.g., CHF).

Chest Pain

The majority of pediatric chest pain cases are noncardiac in origin and benign in nature. Common causes include musculoskeletal or chest wall pain, costochondritis, asthma exacerbations, pneumonia, pleurisy, gastritis, and gastroesophageal reflux. An unusual cause of acute, nonradiating, left-sided chest pain in the adolescent is referred to as the precordial catch syndrome (also known as Tachycardia Syncope). The pain, which is located in the left periapical area of the chest wall, occurs
suddenly, often is exacerbated during inspiration, generally is not reproducible with chest wall compression, and usually resolves within a few minutes. Patients may state the pain took their breath away or they were afraid to move; usually it is of short duration and not associated with dysrhythmias or other sequelae. The cause is unknown and findings on physical examination, chest radiograph, ECG, and echocardiogram are all normal in these patients.

Chest pain or syncope on exertion may be due to an underlying cardiac condition and deserves a more thorough investigation, especially if there is a positive family history of sudden unexplained death in young adulthood. Myocardial involvement secondary to drug abuse (e.g., cocaine, amphetamines, crystal methamphetamine) should always be considered as a potential cause in any adolescent patient who presents with chest discomfort or pain. Pulmonary embolism is a possible cause of chest pain, especially in pregnant adolescent females or those who are taking oral contraceptive agents. The rare though life-threatening condition of aortic dissection must always be considered as a cause of chest pain in a patient with physical examination stigmata that are suggestive of a collagen vascular disorder, such as Marfan’s syndrome. Patients with a known congenital heart defect or an acquired cardiac disorder (e.g., Kawasaki disease, acute rheumatic heart disease, myocarditis, pericarditis, cardiomyopathy) who present with chest pain also deserve a more thorough diagnostic evaluation.

Physical Examination

General Appearance and Pulses

All four extremities should be palpated for the presence and quality of pulses. The brachial and femoral pulses are the easiest to feel in infants. Bounding pulses are typically present in infants with a patent ductus arteriosus. Coarctation of the aorta should be suspected in any child with strong pulses in the upper extremities but weak pulses in the lower extremities. The pulse may be weak and thready in all extremities in a child who presents with CHF and shock.

Vital Signs and Blood Pressures

A mild resting tachypnea or tachycardia may be the only clinical clue to an underlying cardiovascular disorder. Age-related variables in heart rates, respiratory rates, and blood pressures often serve as a source of frustration and confusion to those clinicians who do not manage pediatric patients on a routine basis. Although there are numerous tables of pediatric vital signs with variations based on sleep or awake states, one can easily recall a rough estimate of the normal pediatric heart rates and respiratory rates based on a simplified table of pediatric vital signs (Table 169-2). The methods to calculate the normal expected blood pressures and hypotensive blood pressures are also listed in Table 169-2.

An accurate blood pressure reading is accomplished by using a cuff that covers two thirds of the upper arm or thigh. A cuff that is too narrow will overestimate the patient’s true blood pressure and a cuff that is too large will underestimate the true blood pressure. Any child with a suspected cardiac disorder should have blood pressures measured in both arms. If the blood pressure in the left arm is significantly lower than the blood pressure in the right arm, a coarctation of the aorta proximal to the origin of the left subclavian artery should be suspected. Blood pressures must also be measured in the thighs in any child with a suspected aortic coarctation or documented hypertensive blood pressures in the upper extremities. The mere presence of femoral pulses does not rule out clinically the possibility of a coarctation of the aorta. Even with an appropriately sized cuff, the blood pressures in the thighs can be 10 to 20 mm Hg higher than the blood pressures in the upper extremities due to the lack of well-designed blood pressure cuffs for the legs. Therefore, if the measured blood pressure in the lower extremities is lower than the blood pressures in the upper extremities, coarctation of the aorta should be suspected. Pulse oximetry readings that are lower in the legs than in the upper extremities are also suggestive of either a coarctation of the aorta or a right-to-left-shunt across a patent ductus arteriosus.

Cardiac Auscultation

The intensity and degree of splitting of the S2 heart sound (which reflects closure of the pulmonic and aortic valves) is extremely important in a pediatric cardiologic evaluation. In normal children, both components (aortic closure and pulmonic closure) of S2 should be heard along the left upper sternal border (the pulmonic area). A widely split and fixed S2 suggests a physiologic problem resulting from either a constant volume overload to the right side of the heart (e.g., atrial septal defect) or a pressure overload to the right side of the heart (e.g., pulmonic stenosis). The classic congenital heart defect that is associated with a widely split and fixed S2 is the atrial septal defect. The intensity of the S2 component may be louder than normal in the child with pulmonary hypertension.

The third heart sound (S3), which is best heard along the lower left sternal border or the apex, can be a normal finding in children and young adults. S3 is produced by a rapid filling of the ventricles and is heard during early diastole, just after the S2 sound. A loud S3, however, is always pathologic and is due to dilated ventricles due to volume overload (e.g., CHF and large ventricular septal defects). The fourth heart sound (S4) occurs late in diastole, just before the S1 sound. The finding of an S4 is due to a decrease in compliance of a stiff, hypertrophic ventricle.

Cardiac murmurs are produced by turbulent blood flow through the heart. The presence of a cardiac murmur may not be associated with an underlying cardiac defect, however. The
location, intensity, quality, timing, and radiation of the murmur determine whether the murmur is suggestive of an underlying cardiac pathologic condition. Although systolic murmurs can be present without any underlying anatomic abnormalities, diastolic murmurs are always considered pathologic in nature. Some of the other criteria that would suggest an underlying anatomic cardiac abnormality are listed in Box 169-4. Murmurs may be very difficult to appreciate in the noisy emergency department setting and given the degree of tachycardia that is often present even in normal infants. However, the location of the murmur may be a valuable clinical tool in determining the underlying anatomic origin of the murmur (Box 169-5).

Murmurs without any underlying anatomic abnormalities or hemodynamic significance are termed innocent or functional murmurs. All innocent murmurs are associated with normal ECGs and normal chest radiographs. Two of the most common innocent murmurs encountered in the pediatric population are the neonatal pulmonic flow murmur (also known as the peripheral pulmonic stenosis murmur) and Still’s murmur. The pulmonic flow murmur of the neonate is due to the relatively thin walls and angulation of the right and left pulmonary arteries at birth. This systolic murmur is best heard at the left upper sternal border with radiation throughout the entire chest, axilla, and back. It usually disappears by 3 to 6 months of age.

Persistence of a systolic murmur in the pulmonic area beyond this period should raise the possibility of a pathologic pulmonary arterial stenosis.

Another common innocent murmur in children is Still’s murmur, which is a systolic murmur that typically occurs in children between 2 and 6 years of age. This systolic murmur is best heard along the left midsternal border. The distinctive quality of this murmur has been described as being “vibratory,” “musical,” “zippy,” and “twanging” and results from turbulent flow. The distinct quality of this murmur helps to distinguish Still’s murmur from a ventricular septal defect murmur, which has a harsher quality. The intensity of Still’s murmur can be increased due to fever, excitement, exercise, or anemia.

The Hyperoxia Test

The hyperoxia test is an important bedside diagnostic tool to help differentiate between cardiac and pulmonary causes of central cyanosis. This test consists of assessing the rise in arterial oxygenation with the administration of 100% oxygen. An arterial blood gas is measured on room air (if tolerated) and repeated after several minutes of high-flow oxygen (100% O₂) is administered; the two blood gas analyses are then compared. When the child is breathing high-flow oxygen, an arterial oxygen partial pressure (PaO₂) of greater than 250 mm Hg virtually excludes hypoxia due to CHD—a “passed” hyperoxia test. An arterial O₂ reading of less than 100 mm Hg (in a child without obvious pulmonary disease) is consistent with a right-to-left shunt and is highly predictive of CHD—a “failed” hyperoxia test. Values between 100 and 250 mm Hg may indicate lesions with intracardiac mixing. Pulse oximetry is not an appropriate substitute for an arterial blood gas; it is not sensitive enough to determine “pass or fail” of the test, since a child breathing high-flow O₂ and registering 100% on pulse oximetry may actually have a PaO₂ of anywhere from 80 to 680 mm Hg. Patients with CHF exacerbation can exhibit respiratory acidosis (low pH and PaCO₂) in addition to a low PaO₂. In contrast, children with compensated cyanotic congenital heart defects may have a normal pH despite a low PaO₂. Patients with congenital heart defects who are not experiencing respiratory failure are unlikely to exhibit elevation in PaCO₂. Any cardiac condition that results in inadequate tissue perfusion (i.e., any of the cyanotic congenital heart defects that manifest in CHF) will exhibit a metabolic acidosis with or without a respiratory compensation.

Arterial Blood Gases

Patients with CHF exacerbation can exhibit respiratory acidosis (low pH and PaCO₂) in addition to a low PaO₂. In contrast, children with compensated cyanotic congenital heart defects may have a normal pH despite a low PaO₂. Patients with congenital heart defects who are not experiencing respiratory failure are unlikely to exhibit elevation in PaCO₂. Any cardiac condition that results in inadequate tissue perfusion (i.e., any of the cyanotic congenital heart defects that manifest in CHF) will exhibit a metabolic acidosis with or without a respiratory compensation.

Hemoglobin/Hematocrit Levels and Serum Electrolytes

The hemoglobin and hematocrit levels may reveal a compensatory physiologic elevation (i.e., polycythemia) in children with cyanotic congenital heart defects. Any concurrent medical illness or blood loss that produces an acute anemia could potentially precipitate an acute deterioration by compromising the oxygen carrying capacity in these children with an underlying congenital heart defect. A hemoglobin or hematocrit level
would also be helpful in evaluating whether a child’s pallor is due to CHF or anemia. Serum electrolytes may be helpful when evaluating children with acute dysrhythmias or suspected metabolic acidosis and those children who are on chronic diuretic therapy.

**Chest Radiograph**

Three features of the chest radiograph (Fig. 169-2) that deserve special attention are (1) the cardiac size (cardiothoracic ratio), (2) the cardiac shape (silhouette), and (3) the degree of pulmonary vascular markings. The easiest method to determine the heart size in children is to determine the cardiothoracic ratio, which is obtained by comparing the largest transverse diameter of the cardiac shadow on the posteroanterior view of the chest radiograph to the widest internal diameter (measured from the inside rib margin to the widest point above the costophrenic angle) of the chest. The normal cardiothoracic ratio in children is approximately 50%. The cardiothoracic ratio is not very accurate in newborns and small infants, in whom a good inspiratory view is rarely obtained." A cardiac silhouette that is larger than normal may be due to a shunt lesion, CHF, or a pericardial effusion. An enlarged heart shadow on a chest radiograph more reliably reflects a problem with volume overload rather than pressure overload. Problems with pressure overload are better represented on the ECG.

The cardiac size can be falsely increased in infants due to the presence of the thymus, which can be seen in the mediastinum on the chest radiograph from birth until about 5 years of age. The thymic borders are typically wavy in appearance and sometimes can be seen as the classic "sail sign" along the superior right heart border (Fig. 169-3). The thymic shadow may not be radiographically visible in infants during times of physiologic stress but should reappear when the infant recovers.

The three classic cardiac silhouettes seen in patients with congenital heart defects are (1) the “boot-shaped” heart of tetralogy of Fallot (Fig. 169-4), (2) the “egg-on-a-string silhouette” of transposition of the great vessels, and (3) the “snowman-shaped” or “figure-of-8 heart” of total anomalous pulmonary venous return.

The degree of pulmonary vascular markings is one of the key factors to consider when working through the differential diagnosis of congenital heart defects. An increase in pulmonary vascularity is present when the pulmonary arteries appear enlarged and extend into the lateral third of the lung fields or if there is an increased vascularity to the lung apices. Another criterion that suggests an increased pulmonary vascularity is when the diameter of the right pulmonary artery in the right hilum on the posteroanterior view of the chest is wider than the internal diameter of the trachea. The differential diagnosis of a cyanotic infant with decreased vascular markings includes tetralogy of Fallot, pulmonary atresia, or tricuspid atresia. The cyanotic infant with increased vascular markings may have transposition of the great vessels, total anomalous pulmonary

venous return, or truncus arteriosus. Increased vascular markings in an acyanotic infant are suggestive of an endocardial cushion defect, ventricular septal defect, atrial septal defect, or a patent ductus arteriosus.

In a normal left-sided aortic arch, the aorta descends to the left of the midline and displaces the tracheal air shadow slightly toward the right of midline above the level of the carina. In contrast to this, the tracheal air shadow may be midline or deviated toward the left in the presence of a right-sided aortic arch. This finding is important to note, since a right-sided aortic arch is found in up to 25% of the children with tetralogy of Fallot. Rib notching secondary to increased collateral blood flow along the intercostal vessels can sometimes be appreciated between the fourth and eighth ribs in older children with undiagnosed coarctation of the aorta but is rarely visualized in children with coarctation of the aorta who are younger than 5 years.

Electrocardiogram

The ECG findings in infants and children can sometimes be problematic because various components of the ECGs change according to the child’s age (Table 169-3). At birth, the muscle mass of the right ventricle is greater than that of the left ventricle; this is demonstrated by right axis deviation on the neonatal ECG. By the end of the first month of life, the left ventricle assumes dominance. By 6 months of age, the left ventricular to right ventricular mass ratio is 2:1, which then reaches the adult ratio of 2.5:1 by adolescence. The durations of the PR interval, QRS complex, and QT intervals all increase with age.

Left axis deviation is present when the QRS axis is less than the lower limit of normal for the child’s age and occurs with left ventricular hypertrophy and left bundle branch block. Right axis deviation is present when the QRS axis is greater than the upper limit of normal for the child’s age and occurs with right ventricular hypertrophy and right bundle branch block. A “superior” QRS axis (0 to −180 degrees with an S wave in aVF greater than the R wave) may be suggestive of an endocardial cushion defect or tricuspid atresia.

Some of the more common indications for obtaining an ECG in a pediatric patient include chest pain, dyspnea, syncope, palpitations, and suspected dysrhythmias. Other indications for obtaining an ECG are in those children with known cardiac disorders who present with signs and symptoms that could reflect an acute decompensation of their underlying disorder. A rare but potentially fatal congenital cardiac abnormality that will demonstrate ECG abnormalities (i.e., ischemic changes) is the condition of the anomalous origin of the left coronary artery. These infants have a history of poor feeding, irritability, and failure to thrive, then suddenly present with cardiogenic shock secondary to myocardial ischemia.

Biochemical Markers

The utility and clinical accuracy of cardiac biochemical markers such as creatinine phosphokinase MB and cardiac troponin-T in the emergency department setting is currently limited in the pediatric population. Plasma homocysteine levels have been studied recently as a possible link to CHF in adults;
however, there are currently no studies regarding plasma homocysteine levels in pediatric cardiac disorders. Several recent studies have evaluated the use of plasma B-type natriuretic peptide levels in the assessment and management of CHF in adults. Studies of B-type natriuretic peptide levels in children have demonstrated a similar correlation of elevated levels in children with CHF, and these also correlated to the clinical symptoms of heart failure and the ejection fraction as measured by echocardiography. The clinician is urged to refer to the particular range of age-specific values from the laboratory kit used at his institution.

## SPECIFIC DISORDERS

### Congenital Heart Disease

#### Perspective

The incidence of CHD in the United States has remained fairly constant at approximately 1%, or 8 to 10 cases per 1000 live births. This equates to approximately 32,000 infants born each year with some form of CHD. Although a large percentage of CHD is now detected with prenatal ultrasonograms, one recent study also recommended routinely measuring pulse oximeter readings in all newborns prior to discharge from the nursery as an additional inexpensive screening tool for CHD.

#### Clinical Features

The age, severity of symptoms, and time of presentation of a child with CHD vary depending on the specific defect, complexity and severity of the defect, and timing of the normal physiologic changes that occur as the fetal circulation transitions to that of a neonate. The more severe or complex CHD lesions may not be clinically apparent immediately after birth. However, as the ductus arteriosus begins to close in the first several weeks of life, cardiac defects with obstructive lesions of the pulmonary or systemic circulations will be unmasked, and these infants will present clinically with acute cyanosis, shock, or both. Even the harsh systolic murmur of a large, isolated ventricular septal defect may not be heard until about the 4th to 6th week of life when the left-to-right shunt across the ventricular septal defect increases due to the decrease in the PVR. In general, the more severe the anatomic defect is (i.e., lack of pulmonary blood flow or lack of systemic blood flow), the earlier in life these conditions will manifest with cyanosis and shock.

Although CHD has been subdivided traditionally into cyanotic and acyanotic conditions, not all CHD lesions will fit neatly into a single category; some of the more complex defects have mixed pathophysiologic effects. Although the exact anatomic diagnosis of a CHD is dependent on echocardiography or cardiac catheterization, establishing the exact anatomic diagnosis is not entirely necessary in the emergency department setting.

#### Diagnostic Strategies

The emergency physician must rely on several key elements of the clinical examination in addition to chest radiograph and ECG findings to narrow the diagnostic possibilities. For example, using the data in Box 169-6, the presence of cyanosis, a grade 3/6 systolic-ejection murmur best heard at the mid-left sternal border, a boot-shaped heart, and decreased pulmonary blood flow on the chest radiograph with evidence of right ventricular hypertrophy on the ECG suggest tetralogy of Fallot. Only a brief discussion of some of the more common CHDs is presented in this chapter.

#### Management

The majority of children who present to the emergency department with shock due to dehydration and hypovolemia are typically given intravenous fluids in 20 mL/kg boluses. However, if a child with a suspected CHD presents to the emergency department in possible cardiogenic shock, one could consider using smaller 10 mL/kg boluses to prevent an iatrogenic complication of fluid overload. Frequent reassessment should be performed and the child’s response after each 10 mL/kg bolus monitored to determine whether additional fluid boluses or inotropic agents are necessary.

</table>
Presence or absence of central or peripheral cyanosis?
Central cyanosis with minimal respiratory distress
(“comfortably blue”) is more suggestive of a CHD rather than a purely pulmonary etiology
Abnormalities in cardiac auscultation?
Murmurs: systolic versus diastolic, location, and radiation
Quality of S1, S2, and the presence of any clicks or gurgles
Change in the degree of central cyanosis with crying?
Worsening of cyanosis with crying suggests a cardiac rather than a purely pulmonary etiology
Response of the PaO₂ to the hyperoxia challenge
(administering 100% oxygen)?
Purely pulmonary causes of cyanosis:
PaO₂ should rise to levels above 250 mm Hg
Cyanotic CHD associated with an increased pulmonary blood flow:
PaO₂ may occasionally reach as high as 150 mm Hg
Cyanotic CHD associated with a decreased pulmonary blood flow:
PaO₂ will not rise over 100 mm Hg

Chest radiograph abnormalities?
Cardiac size and shape (one of the three classic cardiac silhouettes)?
Boot-shaped heart: tetralogy of Fallot (TOF)
Egg-on-a-string silhouette: transposition of the great vessels
Snowman-shaped or figure-of-eight heart: total anomalous pulmonary venous return (TAPVR)
Degree of pulmonary blood flow?
Increased (acyanotic): atrial septal defect, Eisenmenger’s syndrome, ventricular septal defect, patent ductus arteriosus, endocardial cushion defects (ECDs)
Increased (cyanotic): transposition of the great arteries (TGA), TAPVR, hypoplastic left heart syndrome, truncus arteriosus
Decreased or normal (acyanotic): pulmonic stenosis (PS), aortic stenosis, coarctation of the aorta
Decreased (cyanotic): TOF, severe PS, Ebstein’s anomaly, tricuspid atresia (TriA), pulmonary atresia, hypoplastic right heart syndrome
Electrocardiographic abnormalities?
Evidence of chamber enlargement: right ventricular hypertrophy, left ventricular hypertrophy, biventricular hypertrophy, right atrial hypertrophy, or left atrial hypertrophy
An abnormal superior QRS axis is suggestive of ECD or TriA

One unique pharmacologic intervention that can be life-saving in infants involves the use of prostaglandin E₁ (PGE₁) to maintain the patency of the ductus arteriosus. CHD that manifests within the first 2 to 3 weeks of life with a sudden onset of cyanosis or cardiovascular collapse is typically due to ductal-dependent cardiac lesions (Box 169-7).⁴

Closure of the ductus arteriosus in patients with these specific cardiac lesions causes life-threatening situations due to either an interruption of blood flow to the lungs producing cyanosis (i.e., tricuspid atresia) or a disruption of blood flow to the systemic circulation producing shock (i.e., hypoplastic left heart syndrome).⁵ Box 169-8 details one suggested method to prepare this potentially lifesaving PGE₁ infusion. The PGE₁ infusion is typically started at 0.05 to 0.1 μg/kg/min (the method of preparation described in Box 169-8). A known adverse reaction of a PGE₁ infusion is apnea; one should perform endotracheal intubation on these infants prior to the initiation of the PGE₁ infusion. Not only will intubation provide a secure airway, but controlled ventilation will also help decrease the infant’s work of breathing. Other adverse reactions of a PGE₁ infusion include fever, seizures, bradycardia, hypotension, flushing, and decreased platelet aggregation.

Acyanotic Congenital Heart Defect

Acyanotic CHD can be further subdivided (Fig. 169-5) into obstructive lesions (i.e., pulmonic stenosis, aortic stenosis, and coarctation of the aorta) and lesions characterized by left-to-right shunts with an associated increase in pulmonary blood flow.
flow (i.e., ventricular septal defects, atrial septal defects, patent ductus arteriosus, and endocardial cushion defects). These acyanotic lesions usually manifest within the first 6 months of life with symptoms of CHF; however, atrial septal defects can remain asymptomatic until adulthood.

### Ventricular Septal Defect

#### Perspective
Ventricular septal defects are the most common congenital cardiac defects and account for 20 to 25% of all cases of CHD. Spontaneous closure occurs in 30 to 40% of all ventricular septal defects overall and in 50 to 70% of smaller ventricular septal defects.14

#### Clinical Features
The degree of symptoms is dependent on the size of the ventricular septal defects and the degree of PVR. Most ventricular septal defects are clinically asymptomatic (minimal to no left-to-right shunting) immediately after birth because of the high PVR. When the PVR decreases to the normal levels at 6 to 8 weeks after birth, left-to-right shunting can then occur and the typical systolic murmur of a ventricular septal defect will then be appreciated. Small ventricular septal defects may remain completely asymptomatic throughout childhood. Approximately 10% of the infants with large ventricular septal defects will eventually develop signs and symptoms of CHF (e.g., poor feeding and poor growth) by 2 to 3 months of age because of the increased pulmonary blood flow. Older children with ventricular septal defects may exhibit signs of decreased exercise tolerance and recurrent pulmonary infections. If moderate to large ventricular septal defects are not surgically corrected, irreversible changes in the pulmonary vasculature may begin to occur as early as 6 to 12 months of age, which will result in an elevation of the PVR and pulmonary hypertension. This in turn can lead to a reversal of the shunt direction across the ventricular septal defect to now become a right-to-left shunt, Eisenmenger’s syndrome, with resultant cyanosis.

#### Diagnostic Strategies
The chest radiograph in children with small ventricular septal defects may be entirely normal, but cardiomegaly with increased pulmonary vascular markings is usually present with untreated moderate to large ventricular septal defects. The ECG of moderate-sized ventricular septal defects typically reveals left ventricular hypertrophy, but biventricular hypertrophy may be present in ventricular septal defects with large left-to-right shunting.

#### Management
All ventricular septal defects, regardless of the size of the defect, are at risk for bacterial endocarditis due to the high velocity of turbulent blood flow through them.

### Atrial Septal Defect

#### Perspective
Atrial septal defects account for 5 to 10% of all cases of CHD. The majority of infants and children with atrial septal defects remain clinically asymptomatic until adulthood. Spontaneous closure has been reported in up to 40% of the cases within the first 5 years of life.14

#### Clinical Features
Large atrial septal defects, or those associated with comorbid conditions such as bronchopulmonary dysplasia, can manifest with symptoms of CHF and pulmonary overcirculation (e.g., dyspnea with feedings, poor weight gain, and frequent lower respiratory tract infections).3 The majority of atrial septal defects are discovered when a suspicious murmur is detected on a routine physical examination. A widely split and fixed S2 is a characteristic finding of atrial septal defects.

#### Diagnostic Strategies
The chest radiograph of children with atrial septal defects will reveal varying degrees of cardiomegaly, right atrial and right ventricular enlargement, and a prominent main pulmonary artery segment and increased pulmonary vascular markings. The ECG will reveal varying degrees of right axis deviation and right ventricular hypertrophy. All patients with un repaired atrial septal defects will develop symptoms if pulmonary hypertension ensues. Patients with large atrial septal defects that are not detected and repaired are at risk for development of Eisenmenger’s syndrome. Unlike ventricular septal defects, uncomplicated atrial septal defects are not associated with high risk of bacterial endocarditis because of the lower turbulence and velocity of blood flow through the atrial septal defects.

#### Management
Like ventricular septal defects, the traditional closure of atrial septal defects required open heart surgery to place a patch over the septal defect. Newer therapies involving closures with septal occluder devices placed via the transcatheter approach have been described.18,20 Antiplatelet therapy during the 6-month period after placement of the device is typically given and is safe and effective in preventing thrombus formation on the surface of the septal occluder device.

### Eisenmenger’s Syndrome
Eisenmenger’s syndrome can occur in any large left-to-right shunt defect that is not surgically corrected. When large left-to-right shunts are left untreated (i.e., large ventricular septal defects and atrial septal defects that are not surgically corrected), irreversible changes can occur in the pulmonary arterioles, leading to pulmonary vascular obstruction and pulmonary hypertension. As the degree of pulmonary hypertension increases, the PVR may then begin to exceed the SVR. This causes right-sided pressures to exceed those on the left, causing right-to-left shunting. The reversal in the direction of shunt flow produces cyanosis. Clinical features of patients who have developed Eisenmenger’s syndrome include chest pain, dyspnea on exertion, and hemoptysis.20

### Coarctation of the Aorta

#### Perspective
Coarctation of the aorta accounts for approximately 8% of all CHD, and up to 50% of patients with coarctation of the aorta also have an associated bicuspid aortic valve.21 The area of coarctation can occur proximal to the insertion of the ductus arteriosus (preductal type) or distal to the insertion of the ductus arteriosus (postductal type). The majority of cases (89%) are of the postductal type.21

#### Clinical Features
The severity of the symptoms and the age at time of presentation are dependent on the location of the coarctation, the degree of narrowing, and the presence of any other associated cardiac defects. Infants with the preductal
type of coarctation of the aorta may also exhibit differential cyanosis if the ductus arteriosus remains open. The upper half of the body is perfused with well-oxygenated blood supplied by the left ventricle and the ascending aorta. However, the lower half of the body will appear cyanotic, as it is largely perfused via right-to-left shunting of deoxygenated blood from the patent ductus arteriosus into the descending aorta.

Infants with the rarer preductal type of coarctation of the aorta will present with signs of circulatory failure and shock when the ductus arteriosus begins to close. Weaker pulses and lower blood pressures in the lower extremities as compared with the upper extremities are the classic physical examination findings in infants and children with coarctation of the aorta.

Most of the asymptomatic postductal cases of coarctation of the aorta are diagnosed as a result of a cardiology referral for a systolic murmur or a hypertension workup, but infants with severe postductal coarctation of the aorta can also present during the first few weeks of life with signs of circulatory failure and shock. If a child is discovered to have hypertension on a routine physical examination, it is mandatory to obtain blood pressure measurements in the lower extremities to assess the possibility of coarctation of the aorta. A systolic blood pressure in the right arm that is 15 to 20 mm Hg greater than that in the legs is sufficient evidence to suspect coarctation of the aorta because the systolic blood pressures in the legs are normally higher than that in the arms. If the systolic pressure in the right arm is higher than that in the left arm, the area of coarctation is probably preductal and located proximal to the origin of the left subclavian artery.

**Diagnostic Strategies.** The chest radiograph will most often reveal a normal-sized cardiac silhouette and normal pulmonary vascular markings, but in children older than 5 years, it may exhibit notching along the lower borders of the posterior fourth to eighth ribs due to the pressure of the dilated collateral vessels. The absence of rib notching, however, does not rule out the possibility of coarctation of the aorta. The ECG typically reveals a left axis and left ventricular hypertrophy.

**Management.** Definitive surgical repair of coarctation of the aorta involves resection of the narrowed section of the aorta with an end-to-end anastomosis. Complications of undiagnosed cases are related to the resultant hypertension and can include heart failure, hypertensive encephalopathy, and intracranial hemorrhages.

### Cyanotic Congenital Heart Diseases

Cyanotic CHDs are a result of either decreased pulmonary blood flow to the lungs or right-to-left shunting of desaturated blood directly into the systemic circulation. These cyanotic CHDs can be further subdivided into those conditions with an increased pulmonary blood flow and those lesions with decreased pulmonary blood flow (Fig. 169-6). The classic cyanotic CHD can be remembered by the “five T’s”: truncus arteriosus, transposition of the great vessels, tricuspid atresia, tetralogy of Fallot, and total anomalous pulmonary venous return. Other forms of cyanotic CHD include Ebstein’s anomaly, pulmonary atresia, severe pulmonary stenosis, hypoplastic left heart syndrome, and hypoplastic right heart syndrome. Because many of these cyanotic heart lesions are usually detected either on prenatal ultrasonographic examinations or in the nursery, only tetralogy of Fallot is covered in this section.

**Tetralogy of Fallot**

**Perspective.** Tetralogy of Fallot accounts for approximately 10% of all cases of CHD and is the most common cause of cyanotic CHD beyond infancy. Tetralogy of Fallot is often associated with other cardiac defects, such as a right-sided aortic arch (25% of patients), atrial septal defect (10% of patients), and anomalous origin of the left coronary artery. Tetralogy of Fallot arises from a single embryologic defect in which the subpulmonic conus fails to expand, resulting in the four abnormalities (Fig. 169-7): (1) right ventricular outflow tract obstruction; (2) a large, unrestrictive, malaligned ventricular septal defect; (3) an overriding aorta that receives blood flow from both ventricles; and (4) right ventricular hypertrophy secondary to the high pressure load placed on the right ventricle by the right ventricular outflow tract obstruction. These anatomic defects collectively result in decreased pulmonary blood flow and varying degrees of right-to-left shunting of deoxygenated blood across the ventricular septal defect.

**Clinical Features.** The degree of cyanosis and the age of presentation are directly dependent on the degree of right ventricular outflow tract obstruction. Infants with tetralogy of Fallot typically have worsening of their cyanosis during crying and feeding. Older children with tetralogy of Fallot may have cyanotic exacerbations during periods of physical exertion. Infants who have milder forms of right ventricular outflow tract obstruction may be acyanotic and are sometimes referred to as having a “pink” tetralogy of Fallot. However, the majority of the cases of tetralogy of Fallot exhibit some degree of cyanosis. Infants with severe right ventricular outflow tract obstruction exhibit profound cyanosis within the first few days of life and may even require a PGE1 infusion to preserve pulmonary blood flow via left-to-right shunting from the aorta into the main pulmonary artery via the patent ductus arteriosus.

The physical examination can reveal varying degrees of cyanosis and a systolic ejection murmur along the left sternal border. Chronic hypoxemia results in a compensatory polycythemia and varying degrees of clubbing of the fingers and toes.

**Diagnostic Strategies.** The chest radiograph of a patient with cyanotic tetralogy of Fallot (see Fig. 169-4) reveals decreased pulmonary vascular markings and a boot-shaped heart (secondary to a concave main pulmonary artery segment along the superior aspect of the left heart border). The heart size in tetralogy of Fallot is normal, and a right-sided aortic arch may be seen in 25% of the cases. The ECG of cyanotic tetralogy of Fallot reveals right ventricular hypertrophy and a right axis deviation. Children with “pink” tetralogy of Fallot may not initially exhibit any degree of right ventricular hypertrophy,
but these acyanotic forms of tetralogy of Fallot gradually develop the cyanotic form by 1 to 3 years of age.

A potentially life-threatening complication of tetralogy of Fallot that can be seen in a patient who presents to the emergency department is the so-called “tet spell,” which has also been referred to as the “hypercyanotic spell” or the “hypoxic spell.” Although these hypoxic spells can occur in children with other forms of CHD, they are most commonly seen in infants and children with tetralogy of Fallot, and hence the term tet spell. These episodes occur most commonly in infants, with a peak incidence between 2 and 4 months of age.

Any event that suddenly lowers the SVR, such as crying or defecation, will produce a large right-to-left shunt across the ventricular septal defect, beginning the vicious cycle of a hypoxic spell. Acute hypovolemia and tachycardia can also precipitate tet spells. The large right-to-left shunt through the ventricular septal defect bypasses the lungs, which then causes a decrease in the PaO₂, an increase in the PCO₂, and a fall in the arterial pH. These metabolic changes then stimulate the respiratory centers in the brain to produce hyperpnea (deep and rapid respirations), which increases the negative intrathoracic pressure during inspiration, causing an increase in the systemic venous blood return to the right side of the heart. This increased volume of blood in the right ventricle is then shunted through the ventricular septal defect through the combination of the existing right ventricular tract outflow obstruction and the acute decrease in the SVR. This in turn further decreases the arterial oxygen saturation, perpetuating the hypoxic spell (Fig. 169-8).

Clinically these hypoxic spells are characterized by periods of hyperpnea (rapid and deep respirations), uncontrollable crying, and worsening cyanosis. Limpness, seizures, cerebrovascular accidents, and even death have been reported with more severe tet spells. During a tet spell, the intensity of the murmur decreases because of less blood flow through the right ventricular tract obstruction and more blood being shunted from the right ventricle to the left ventricle through the ventricular septal defect.

**Management.** The overall treatment goals for tet spells (Box 169-9) are: (1) increasing the SVR, (2) abolishing the hyperpnea, and (3) correcting the metabolic acidosis. Although supplemental oxygen should be provided, this alone will not reverse a tet spell, since there is a decrease in the amount of

**Figure 169-7.** Diagrammatic representation of the right-to-left shunting that occurs in tetralogy of Fallot. Some of the deoxygenated blood (thick blue arrow) in the right ventricle is shunted across the ventricular septal defect (VSD) into the left ventricle. This deoxygenated blood mixes with the well-oxygenated blood from the lungs (red arrow). The blood that is ejected out through the overriding aorta (OAo) therefore contains blood of mixed oxygenation (purple arrows). The amount of deoxygenated blood that is shunted through the VSD (thick blue arrow) is dependent on a combination of factors, including the severity of right ventricular outflow tract obstruction (OB), the size of the VSD, and the degree of systematic vascular resistance (SVR). When the SVR falls (as occurs during a tet spell), more deoxygenated blood from the right ventricle will be shunted across the VSD into the systemic circulation, which results in hypoxia, metabolic acidosis, and worsening cyanosis.

**Box 169-9**

**Management of Tetralogy of Fallot Hypoxic Spells**

- Place the infant in the knee-to-chest position to increase the SVR, which decreases the right-to-left shunt across the VSD.
- Provide supplemental oxygen (limited value by itself).
- Morphine: 0.1–0.2 mg/kg intravenously (IV) or intramuscularly (IM)
- Fentanyl: 1 µg/kg/dose IV or IM as an alternative to morphine
- Sodium bicarbonate: 1 mEq/kg IV
- Consider ketamine: 1–2 mg/kg IV or IM
- Consider propranolol: 0.01–0.2 mg/kg IV
- Consider phenylephrine: 0.01–0.02 mg/kg IV
pulmonary blood flow and an increase in the amount of right-to-left shunting across the ventricular septal defect. The infant should be picked up and placed in a knee-to-chest position. Older children can be placed in the squatting position. Both maneuvers are believed to increase the SVR and decrease the amount of systemic venous blood return to the right side of the heart. Morphine (0.1–0.2 mg/kg) has been traditionally given intramuscularly to suppress the respiratory center and thereby abolish the hyperpnea. A theoretical adverse effect of morphine, however, is that it can cause systemic vasodilation (further decreasing the SVR) via endogenous histamine release.22 Although there are no current studies evaluating the use of other medications that may also suppress the respiratory centers, fentanyl and midazolam could be utilized for the same effect without the potential risk of endogenous histamine release. Ketamine (1–2 mg/kg intravenously or intramuscularly) has also been suggested for its sedative effect as well as for its effect on increasing the SVR.23 Sodium bicarbonate can be given to correct any metabolic acidosis and reduce the respiratory center–stimulating effects of acidosis. Most infants respond to these measures and exhibit an improvement in their oxygenation and a decrease in their degree of cyanosis. Those infants whose condition does not improve with the above measures may require a vasopressor such as phenylephrine to increase the SVR and thereby decrease the degree of right-to-left shunting across the ventricular septal defect. An intravenous fluid bolus may also be considered to increase the volume of blood flow through the pulmonary artery. Propranolol has also been used as an adjunct to break the cycle of a tet spell. Although the exact pharmacophysiologic mechanisms by which propranolol accomplishes this is uncertain, it is thought to increase the SVR and perhaps promote an increase in the pulmonary blood flow by reducing spasms of the right ventricular outflow tract obstruction.

Palliative surgical procedures to increase the amount of blood flow temporarily to the pulmonary arteries are performed in infants with severe cyanotic tetralogy of Fallot. The most commonly performed procedure is the modified Blalock-Taussig shunt, in which an anastomosis is created between the subclavian artery and the ipsilateral pulmonary artery. Definitive surgical repair of tetralogy of Fallot consists of closing the ventricular septal defect and opening the right ventricular outflow tract obstruction by resection of the infundibular tissue. The mortality rate is 5 to 10% within the first 2 years after definitive surgical repair in uncomplicated tetralogy of Fallot cases. Complications that can occur after definitive surgical repair include complete heart block, ventricular dysrhythmias, and right bundle branch block (secondary to the right ventriculotomy). Bacterial endocarditis prophylaxis is still recommended after the definitive surgical repair of tetralogy of Fallot.

**Postoperative Complications of Congenital Heart Defects**

A variety of postoperative complications can be seen in patients who present to the emergency department weeks to months after cardiac surgery. The types of complications that could occur in each case depend on the original underlying cardiac defect as well as on the surgical procedure that was used to correct that defect. Some of the complications that may be seen in the emergency department include thrombosis of a shunt-conduit with decreased flow, increased shunt-conduit flow with resultant CHF, atrial and ventricular dysrhythmias, heart blocks, myocardial ischemia, and endocarditis. The size of the cardiac silhouette and the degree of pulmonary blood flow visualized on the chest radiograph may provide valuable clues as to whether there is an increased or decreased blood flow through a surgical conduit that was created to provide an improvement in blood flow to the pulmonary system.25 Comparison of the child’s other postoperative chest radiographs can help to determine whether there has been a change in the heart size and pulmonary vascularity.

The postpericardiotomy syndrome is an inflammatory peri-carditis that can occur 1 to 6 weeks after any surgical procedure that involved a pericardiotomy. This immunologic phenomenon is believed to occur as a sequela of blood in the pericardial sac. This syndrome is characterized by fever, chest pain, and a pericardial effusion. A pericardial friction rub may be heard, depending on the amount of fluid that accumulates in the pericardial sac. The chest radiograph may reveal an enlarged cardiac silhouette, and the echocardiogram will confirm the diagnosis. Pericardiocentesis is rarely required but may be necessary if the amount of pericardial effusion is significant enough to cause a pericardial tamponade. The majority of cases will resolve within 2 to 3 weeks with bedrest and non-steroidal anti-inflammatory medication.

Many of the above-mentioned postoperative complications, including the postpericardiotomy syndrome, can be avoided in children who undergo closure of patent ductus arteriosus, atrial septal defects, and ventricular septal defects via the transcatheter placement of various occluder devices.

**Respiratory Syncytial Virus Infections in Infants and Children with Congenital Heart Defects**

Respiratory syncytial virus (RSV) is the most common cause of lower respiratory tract infections in infants and children worldwide, with the majority of children being infected at least once by 2 years of age. Reinfection occurs commonly throughout life.20 RSV lower respiratory tract infections account for more than 125,000 pediatric admissions annually in the United States, with a fatality rate of 6.3 deaths per 100,000 patients up to 4 years of age (Box 169-10).27,28 Children with CHD who develop RSV infections tend to have a higher rate of intensive care unit admissions and require mechanical ventilation more frequently than those children who do not have CHD. Children with CHD who require hospitalization for RSV have a mortality rate that is two to six times greater than that of children without CHD.27,28 RSV is responsible for a mortality rate of 40% in infants with CHD and up to 70% in infants with CHD and associated pulmonary hypertension.

Currently there are two products that can be used to prevent RSV infections. Both of these preparations require monthly administration prior to the onset of the peak RSV season, which typically runs from November through March in most states. The two currently available preparations are (1) palivizumab (Synagis), which is a humanized monoclonal antibody administered intramuscularly at a dose of 15 mg/kg and (2) RSV immunoglobulin (RespiGam), which requires intravenous administration at a dose of 750 mg/kg (which is equal to 15 mL/kg) and must be administered over a 4-hour period.26 The use of palivizumab in the prevention of RSV infections in high-risk infants and children has largely replaced RSV
immunoglobulin because palivizumab can be given intramuscularly, requires a 100-fold lesser volume, and has a 50-fold smaller protein load than RSV immunoglobulin.²⁹

In 1998, the Food and Drug Administration gave approval for the use of palivizumab in preventing RSV lower respiratory tract infections in selected infants and children who were deemed to have a higher risk of severe infections. During the 4-year period from 1998 to 2002, several multicenter studies involving more than 24,000 subjects (including data from the Palivizumab Outcomes Registry) have demonstrated the efficacy of palivizumab in preventing hospitalizations of high-risk infants and children.³⁰ During this same 4-year period, another multicenter study involving six countries demonstrated a 45% relative reduction in hospitalization of 1287 high-risk children younger than 2 years with CHD who were given 15 mg/kg monthly intramuscular injections of palivizumab over a 5-month period.²⁹ This study also demonstrated a significant reduction in the total number of hospital days, supplemental oxygen requirement, total number of days in the intensive care unit, and total number of days requiring intubation in the group that received the monthly palivizumab intramuscular injections. Based on these results, the Food and Drug Administration in September 2003 gave approval for the use of palivizumab in infants and children with hemodynamically significant CHD (Box 169-11). The American Academy of Pediatrics emphasizes that prophylaxis with palivizumab should be initiated prior to the onset of the RSV season. Because RSV can persist on environmental surfaces for several hours, the best method to prevent the spread of RSV-contaminated secretions within the emergency department setting is meticulous hand washing and wearing a mask when caring for children with a documented or suspected RSV infection.

**Congestive Heart Failure**

**Perspective**

Congestive heart failure is defined as a clinical syndrome in which the cardiac output is unable to meet the hemodynamic and metabolic demands of the body. Although there is a wide array of causes of CHF, the primary cause in infants and children is CHD, which results in volume or pressure overload. Other causes of CHF include the anomalous left coronary artery in infants, myocarditis, endocarditis, rheumatic heart disease, pericardial effusions, anemia, cardiomyopathies, systemic hypertension, hypothyroidism, electrolyte imbalances, cardiac toxins, and dysrhythmias that compromise cardiac output.

CHF can result from a derangement in one of the four primary determinants of normal cardiac function: (1) excessive preload (e.g., large left-to-right shunts and severe chronic anemia); (2) decreased cardiac contractility (e.g., myocarditis); (3) excessive afterload (i.e., left-sided obstructive lesions); and (4) rhythm abnormalities that compromise cardiac output or stroke volume (e.g., paroxysmal supraventricular tachycardia and severe forms of heart block). The treatment of CHF depends on which of these four primary determinants of normal cardiac function are compromised. For example, inotropic agents and diuretics may be required in a child with volume overload and decreased cardiac contractility, whereas vasodilating agents may be required in a child with CHF due to an increased afterload.

**Clinical Features**

Although the clinical manifestations of CHF depend on the exact pathophysiologic cause of the CHF, common presenting signs and symptoms include tachycardia, a gallop rhythm, tachypnea with rales, hepatomegaly, peripheral edema, and decreased peripheral perfusion of the extremities. Wheezing and a chronic cough may also be the presenting symptoms of CHF.

**Diagnostic Strategies**

The chest radiograph typically reveals an enlargement of the cardiac silhouette and varying degrees of pulmonary congestion. An echocardiogram will be able to assess the ejection fraction as well as to identify underlying anatomic defects. Plasma B-type natriuretic peptide has been reported to be helpful in differentiating cardiac from pulmonary etiologies of dyspnea in children.³¹ Other diagnostic studies to consider are case specific and depend on the suspected cause of the child’s CHF.

**Management**

Acute stabilization of any child who presents with CHF includes administration of supplemental oxygen and agents to augment cardiac contractility and to improve cardiac output. Children who present in severe respiratory distress secondary to pulmonary edema may require intubation to support oxygenation and ventilation. Children with respiratory distress and air hunger due to pulmonary congestion may also benefit from elevation of the head and upper torso in addition to morphine sulfate (0.05–0.1 mg/kg/dose) administration. Continuous positive airway pressure or biphasic positive airway pressure ventilation may be useful initially to avert the need for endotracheal intubation. Plasma B-type natriuretic peptide levels have been shown to be elevated in children with CHF and have also been used to monitor the response to treatment regimens in patients with CHF.¹¹

Diuretics and inotropic agents are the mainstay of treatment for the majority of children with CHF. Furosemide (Lasix) in a dose of 1 mg/kg is the most common loop diuretic used to increase renal perfusion and improve urine output. Digoxin has remained the most widely used inotropic agent to treat CHF in children (Table 169-6). With the proper use of furosemide and digoxin, most children with CHF will demonstrate a favorable response. The narrow therapeutic index of digoxin requires that levels be monitored very closely to prevent iatrogenic digoxin toxicity, which could cause a worsening of the preexisting CHF.
Digoxin is a cardiac glycoside that is used to increase contractility and slow heart rate. It is primarily used to treat heart failure and certain arrhythmias. Digoxin is metabolized by the liver and excreted by the kidneys. In renal impairment, digoxin levels can rise, leading to toxicity. The oral dose is usually 0.1–1.0 µg/kg every 8–12 hours, but it can be divided into a twice-daily dosing regimen if needed. The intravenous dose is equal to 75% of the oral dose (except in children >10 years old, in whom the intravenous dose is the same as the oral dose).

The total daily digitalizing dose (TDD) is determined based on the initial dose, with subsequent doses being 5–10% of the TDD given every 8–12 hours. The daily maintenance dose is divided into a twice-daily dosing regimen (except in children >10 years of age, in whom the maintenance dose can be given as a single daily dosing regimen). Oral digoxin is supplied as a 50 µg/mL elixir. A lower dosing regimen may be required in those patients with renal failure since digoxin is excreted by the kidneys.

Other inotropic agents that are used for the treatment of CHF in infants and children are dopamine, dobutamine, and epinephrine (Table 169-7). Standardized drips have been established and have essentially replaced the “rule of six.”32

Dopamine is an endogenous catecholamine with complex cardiovascular effects. It can increase renal blood flow in low doses (2–5 µg/kg/min) and increase the cardiac contractility and heart rate in moderate doses (5–10 µg/kg/min). Dopamine stimulates cardiac beta₁-adrenergic receptors both directly and indirectly through the release of endogenous noradrenaline stored in the cardiac sympathetic nerves. Due to this, some of the inotropic effects of dopamine may be reduced in those patients with decreased endogenous myocardial noradrenaline stores (i.e., patients with chronic CHF and neonates). At higher doses (10–20 µg/kg/min), dopamine will also increase the SVR, but excessive vasoconstriction may compromise end-organ perfusion at infusion rates greater than 20 µg/kg/min. If additional inotropic effects are required, the addition of either dobutamine or epinephrine infusions may be preferable to increasing the dopamine infusion greater than 20 µg/kg/min. The major toxicities of dopamine are tachycardia, vasoconstriction, and ventricular ectopy.

Dobutamine is a synthetic catecholamine with more selective cardiac inotropic effects and some beta₂-adrenergic vasodilatory effects. It is not a vasoressor per se, but could be a good adjunct in the treatment of low cardiac output states that are secondary to poor myocardial function. Dobutamine may have an advantage over dopamine in that it has fewer arrhythmogenic effects than dopamine and may also have a more direct effect on the enhancement of coronary blood flow. The main toxicities of dobutamine are tachycardia, ventricular ectopy, and hypotension.

Epinephrine is a potent inotrope and chronotrope and also increases the SVR. Epinephrine is useful in scenarios in which poor cardiac output is also associated with diminished systemic vascular tone. Toxicities associated with epinephrine include tachydysrhythmias, severe hypertension, hyperglycemia, lactic acidosis, and hypokalemia. Amrinone and milrinone are newer inotropic agents that also have peripheral vasodilatory effects. These agents have been used in improving cardiac index in septic shock and in prevention of low cardiac output states for children with CHD. Side effects of these medications include profound hypotension, dysrhythmias, hypersensitivity reactions, fever, hepatotoxicity, and thrombocytopenia.

Another vasodilating medication that has been used for arterial and venous dilatory effects is nitroprusside. Nitroprusside has potent vasodilatory effects on both the systemic and pulmonary circulatory systems. This medication has a prompt onset of action and a short duration of action. Nitroprusside must be used cautiously in patients with either hepatic and/or renal impairment to avoid cyanide toxicity (severe metabolic acidosis and coma) or thiocyanate toxicity (irritability, seizures, abdominal pain, and vomiting).

### Pediatric Dysrhythmias

#### Perspective

Dysrhythmias are not as common in children as they are in adults. The most common cause of cardiopulmonary arrest in infants and children is the untreated progression of respiratory failure or shock rather than a primary cardiac dysrhythmia.33 Therefore, the most common arrest rhythm that will confront the emergency physician will be asystole or bradycardia rather than ventricular fibrillation or ventricular tachycardia. When confronted with a child with a primary cardiac dysrhythmia, the physician must identify and treat the underlying cause quickly and systematically. Children who are at risk for developing dysrhythmias are listed in Box 169-12. Various medications, drugs, and toxins can also precipitate dysrhythmias in children. Even those medications that are used to treat underlying cardiac problems such as digoxin, amiodarone, and procaïnamide can themselves precipitate dysrhythmias. Drugs of abuse (e.g., cocaine and crystal methamphetamine) and overdose of prescription medications (e.g., cyclic antidepressants) should always be considered when evaluating any previously healthy adolescent patient who presents with an acute dysrhythmia.

Pediatric dysrhythmias can be divided into three broad categories of rhythms based on their effect on the child’s pulse: slow (sinus bradycardia and heart blocks), fast (supraventricular tachycardia or ventricular tachycardia with a pulse), or absent (ventricular tachycardia without a pulse, ventricular fibrilla-
Conditions Associated with a High Risk of Developing Dysrhythmias

- Congenital heart defects (uncorrected defects and postoperative complications)
- Congenital complete heart blocks (e.g., maternal systemic lupus erythematosus)
- Myocarditis
- Rheumatic heart disease
- Kawasaki disease with involvement of the coronary arteries
- Cardiomyopathy
- Prolonged QT syndrome
- Aberrant atrioventricular conduction pathways (e.g., Wolff-Parkinson-White syndrome)
- Electrolyte abnormalities (e.g., potassium, calcium, and magnesium disturbances)
- Commotio cordis
- Profound hypothermia
- Hypoxia

Tachydysrhythmias

Sinus Bradycardia. Bradycardia is defined as a heart rate that is slower than the lower limit of normal for a child’s age. Based on the current definition by the American Heart Association (AHA) guidelines in Pediatric Advanced Life Support (PALS), clinically significant bradycardia in children is defined as a heart rate slower than 60 beats per minute that is associated with poor systemic perfusion. Bradycardia is poorly tolerated in infants and children because they are not physiologically capable of increasing their stroke volume to maintain an adequate cardiac output in the face of significant bradycardia.

The most common cause for symptomatic bradycardia in infants and children is hypoxia. Therefore, the first step in the management of symptomatic bradycardia in children is to ensure adequate oxygenation and ventilation before automatically reaching for medications or pacing. Epinephrine is the first-line medication when treating symptomatic bradycardia in children that is not responsive to appropriate oxygenation and ventilation. This is in contrast to the treatment of bradycardia in adults, in which atropine is considered to be the first-line medication. If additional doses of intravenous or intraosseous epinephrine are required when treating symptomatic bradycardia, the dose should remain at standard dosing (0.01 mg/kg) and not be increased to the high dose (0.1 mg/kg) according to AHA and PALS guidelines. Atropine will have no effect on the denervated heart. If vascular access is not available, both epinephrine and atropine can be administered via the tracheal tube, although the intravenous route is preferred.

Other causes of bradycardia include hypothermia, increased intracranial pressure, heart blocks (congenital and acquired), a denervated heart status post–cardiac surgery, hypothyroidism, sick sinus syndrome, and various medications and toxins (e.g., digoxin, beta-blockers, calcium channel blockers, and cholinergic agents). One should consider emergency pacing for Mobitz type II second-degree atrioventricular block, complete third-degree heart block, or sick sinus syndrome.

Athletic adolescent patients may have resting baseline heart rates slower than 60 beats per minute and do not require emergency treatment if they are completely asymptomatic.
Summary of Pediatric Dysrhythmia Treatment Options and Defibrillation, Cardioversion, and Medication in Resuscitation

Figure 169-9. An example of an electrocardiogram showing a wide-complex supraventricular tachycardia at a rate of approximately 270 beats/min in an infant with Ebstein’s anomaly of the tricuspid valve. This infant was in supraventricular tachycardia for approximately 2 days and presented with an acute exacerbation of her congestive heart failure, as evidenced by the cardiomegaly on the chest radiograph (see Fig. 169-10). Note that the cardiothoracic ratio in this infant is approximately 70%.

Infants with supraventricular tachycardia typically present with very nonspecific symptoms, such as fussiness and difficulty feeding. Although healthy infants can generally tolerate supraventricular tachycardia with heart rates approaching 300 beats per minute, if left untreated supraventricular tachycardia may begin to produce signs of CHF and shock. Older children with supraventricular tachycardia commonly present with palpitations, difficulty breathing, and chest discomfort.

Clinical Features and Diagnostic Strategies. The width of the QRS interval in patients with pediatric supraventricular tachycardia is most commonly narrow-complex, with heart rates in infants usually greater than 220 beats per minute (Fig. 169-11). It is sometimes difficult to distinguish between sinus tachycardia and supraventricular tachycardia (Table 169-8).

Management. Management of supraventricular tachycardia depends on the hemodynamic stability of the child. If the child with supraventricular tachycardia is hemodynamically unstable and intravenous access is not available, immediate cardioversion starting at 0.5 to 1 joules/kg is the treatment of choice. If the child does not convert with this initial cardioversion attempt, the energy dose can be doubled up to 2 joules/kg on subsequent attempts. If the child is hemodynamically stable, vagal maneuvers or adenosine, or both, can be attempted initially before cardioversion, depending on the individual case scenario. Regardless of the method selected to convert the supraventricular tachycardia, a continuous rhythm strip should always be run to document the response to each conversion attempt. Vagal maneuvers (e.g., a bag containing a slurry of crushed ice and water to the face, blowing on an occluded straw, or blowing on the tip of a syringe) can be attempted before adenosine administration only in the child with hemodynamically stable supraventricular tachycardia. Application of ice to the face has been demonstrated to be a fairly effective method of converting supraventricular tachycardia in infants and children.40,41 One method to perform this maneuver is to fill a plastic bag or surgical glove with a slurry of crushed ice and water, which is then placed over the infant’s forehead, eyes, and bridge of the nose for 10 to 15 seconds. Care must be taken not to occlude the nose or mouth with the bag of ice water. External ocular pressure should be avoided, as it can be dangerous in children because excessive pressure...
can lead to a ruptured globe. Carotid massage is less effective and is not recommended as a vagal maneuver in infants or children.34

The initial dose of adenosine in children is 0.1 mg/kg with a maximum initial dose of 6 mg. If this initial dose of adenosine fails to convert the supraventricular tachycardia, the dose is then doubled to 0.2 mg/kg with a maximum of 12 mg/dose. This 0.2 mg/kg dose of adenosine can be attempted once more during the third adenosine dose. Elective cardioversion or esophageal overdrive pacing under conscious sedation may be

Figure 169-11. Three electrocardiographic examples of classic narrow-complex supraventricular tachycardia in children. The heart rate is approximately 240 beats/min in the first two examples (A and B) and approximately 270 beats/min in the third example (C).
Figure 169-12. An example of adenosine-induced wide-complex tachycardia. A dose of 6 mg of adenosine was administered to this previously healthy 15-year-old girl who presented with a 6-hour history of palpitations. She had no previous cardiac problems except for intermittent palpitations in the past that always resolved spontaneously without any medical interventions. Once adenosine blocked the conduction through the atrioventricular node, a wide-complex tachycardia appeared on the electrocardiogram (ECG), which was probably due to antegrade conduction through an accessory pathway. During the 30 seconds of this wide-complex tachycardia, the patient remained alert with excellent perfusion parameters. This wide-complex tachycardia then spontaneously converted to normal sinus rhythm. Although the patient’s postconversion ECG did not reveal an accessory pathway, Holter monitoring 1 month later detected the classic ECG findings of Wolff-Parkinson-White syndrome.

required in children who fail to convert with adenosine. Complications of adenosine administration include asystole and various dysrhythmias, including adenosine-induced wide-complex tachycardia (secondary to an occult accessory conduction pathway) (Fig. 169-12). The use of verapamil to convert supraventricular tachycardia in infants and younger children should be avoided because of the high incidence of profound hypotension and cardiovascular collapse when this medication is administered in this age group.34

Once the patient has been converted to sinus rhythm, a 12-lead ECG should be obtained to assess for the possibility of Wolff-Parkinson-White syndrome or any other underlying conduction abnormalities that may have predisposed the child to developing the supraventricular tachycardia.

Atrial Flutter and Atrial Fibrillation. Both atrial flutter and atrial fibrillation are rare in children and are usually associated with underlying heart conditions (i.e., CHD, status post–open heart surgical procedures that involved the atria, myocarditis, and digoxin toxicity). Hemodynamic stability of these two dysrhythmias depends on the rate of the ventricular response. Cardioversion is the treatment of choice for children who present with hemodynamically unstable atrial flutter or atrial fibrillation. The initial treatment priority in patients with hemodynamically unstable atrial flutter or atrial fibrillation is first to slow down the rate of the ventricular response with medications such as digoxin, beta-blockers, or diltiazem. Once the ventricular rate is controlled, the rhythm can then be converted and suppressed with amiodarone, procainamide, or elective cardioversion. If the patient who presents with atrial flutter and atrial fibrillation is known to have an underlying Wolff-Parkinson-White syndrome, the four medications that should be avoided are the “A-B-C-D” medications (adenosine, beta-blockers, calcium-channel blockers, and digoxin), because all of these medications only block conduction down the atrioventricular node while leaving the accessory pathway wide open to conduct the atrial tachycardia to the ventricles at a potentially lethal rate.42 Under these circumstances, amiodarone, procainamide, or cardioversion would be the safer alternative. Consultation with the cardiologist and initiation of anticoagulation should also be considered before conversion of either of these two atrial dysrhythmias in the hemodynamically stable patient to prevent a thromboembolic complication.

Ventricular Tachycardia. Ventricular tachycardia is not a common dysrhythmia in children. The majority of children with ventricular tachycardia have an underlying condition such as status post–cardiac surgery, myocarditis, prolonged QT syndrome, drug or toxin exposures (e.g., cyclic antidepressants), or electrolyte abnormalities. The treatment of ventricular tachycardia will depend on whether a pulse is present and on the hemodynamic status of the patient (Box 169-14). Torsades de pointes is a unique type of polymorphic ventricular tachycardia that is characterized by QRS complexes that change in polarity and amplitude. Prolonged QT syndrome, underlying congenital cardiac defects, hypomagnesemia, and various medications (e.g., cyclic antidepressants) have all been identified as known causes of torsades de pointes. The treatment of choice is intravenous magnesium. Class IA (i.e., procainamide) and class III (i.e., amiodarone) antidysrhythmic agents are both contraindicated in the treatment of torsades de pointes, because these two antidysrhythmic agents are capable of prolonging the QT interval, which could then precipitate the degeneration of the torsades de pointes into a more lethal rhythm.

CLINICAL CONDITIONS IN WHICH BACTERIAL ENDOCARDITIS SHOULD BE SUSPECTED IN A CHILD WITH AN UNDERLYING ANATOMIC CARDIAC DEFECT

Fever of unknown etiology
A change in the quality of the preexisting heart murmur or the presence of a new heart murmur
Development of a neurologic deficit (secondary to central nervous system emboli)
New-onset microscopic hematuria
Splenomegaly
Petechiae
Splinter hemorrhages involving the conjunctiva, nail beds, palms, or soles
Myalgias

Pulseless Rhythms

Ventricular Fibrillation and Pulseless Ventricular Tachycardia. Ventricular fibrillation and pulseless ventricular tachycardia account for approximately 10% of out-of-hospital cardiac arrest cases in which a terminal rhythm was recorded.43,44 The survival rate for out-of-hospital ventricular fibrillation and pulseless ventricular tachycardia can be as high as 30%, whereas the survival rate from asystolic cardiac arrest is less than 1%.31 In a recent study of in-hospital cardiac arrests, a shockable rhythm was present during some point of the resuscitation in 25% of the children.45 The survival rate of children who initially exhibited shockable rhythms were higher than those children who presented with nonshockable rhythms. However the survival rates in those children who later developed a shockable rhythm at some time during their resuscitation were not as good.45–47 Ventricular fibrillation should also be suspected as the arrest rhythm in cases of comatose cordis or in cases of sudden cardiac arrest. Current arrhythmia detection algorithms for automated external defibrillators (AEDs) appear to have a high sensitivity and specificity for detecting shockable rhythms in children; in July 2003 the AHA gave their approval for the use of AEDs in children 1 to 8 years of age (class IIB recommendation). When an AED is to be used on a child younger than 8 years (or <25 kg) the use of a pediatric attenuator device is strongly recommended in order to deliver a more pediatric-appropriate dose of defibrillation.48,49 The American Academy of Pediatrics (AAP) also recently supported the use of AEDs in children.50,51 There currently is still not enough clinical evidence to recommend for or against the use of AEDs in infants under 1 year of age.

The treatment algorithm and medication dosages for ventricular fibrillation and pulseless ventricular tachycardia are listed in Box 169-13. The 2005 PALS arrhythmia algorithms are basically the same as the 2000 treatment guidelines with one major change. Based on the 2005 PALS guidelines, ventricular fibrillation and pulseless ventricular tachycardia are now treated with single defibrillations followed immediately by 2 minutes of uninterrupted cardiopulmonary resuscitation (CPR).48 Although a single shock with a biphasic defibrillator has a high likelihood of terminating ventricular fibrillation, the resulting rhythm is typically a nonperfusing rhythm, which therefore requires CPR in order to maintain perfusion to the heart and brain until normal cardiac contractility can resume.40,52 Epinephrine is given with the second defibrillation and antiarrhythmic agents are added to the treatment algorithm with the third defibrillation. Although biphasic defibrillators can convert ventricular fibrillation at lower dosages than the previous monophasic defibrillators in adults, until more data are gathered on biphasic defibrillation dosages in children, the current AHA recommendation for pediatric defibrillation with biphasic defibrillators remains the same as for monophasic defibrillators (i.e., starting at 2 joules/kg followed by 4 joules/kg).

Asystole and Pulseless Electrical Activity. Asystole is the most common rhythm found in cases of out-of-hospital cardiac arrest in children and is associated with a less than 1% chance of survival.31–33 “The use of high-dose epinephrine has been deemphasized in the 2005 PALS guidelines.”50 The treatment algorithm and medication dosages for asystole and pulseless electrical activity are listed in Box 169-13. Pulseless electrical activity can either be a slow or fast rhythm and have a narrow or wide QRS complex.

The key to survival from any pulseless electrical activity rhythm is to rapidly identify and correct the underlying cause. The etiologies for pulseless electrical activity can be remembered by the “6 H’s and 5 T’s”: hypovolemia, hypoxemia, hypothermia, hydrogen ion (acidosis) hypo-/hyperkalemia, hypoglycemia, hypothermia, toxins, tamponade, tension pneumothorax, thrombosis, and trauma.53–55 The most common cause of pulseless electrical activity in children is profound hypovolemia. Therefore, an intravenous fluid bolus should always be considered as a therapeutic option during the treatment of pulseless electrical activity.

Bacterial Endocarditis

Perspective

Bacterial endocarditis involves an infection of the endothelial surfaces of the heart with a propensity for the valves. The incidence of bacterial endocarditis in children may be increasing slightly due to the many advances in surgical technology that are now allowing many children with very complex congenital heart lesions to survive. Children with indwelling intravenous lines with or without underlying CHD are also at risk for developing bacterial endocarditis. Although bacterial endocarditis most commonly occurs in children with an underlying CHD or an acquired cardiac lesion (e.g., acute rheumatic valvular heart disease), it can also occur in patients with no underlying anatomic defects of the valves or endocardium. In a series of 62 children with bacterial endocarditis, 19 (30%) of the children had normal cardiac anatomy.50

Factors that predispose children with underlying anatomic cardiac defects to bacterial endocarditis include dental procedures and other surgical procedures involving the respiratory, gastrointestinal, or genitourinary tracts. Those cardiac lesions with a more turbulent blood flow or a higher flow velocity are more prone to developing bacterial endocarditis secondary to a greater risk of endothelial surface damage, which then increases the risk of platelet deposition and vegetation formation. Cardiac lesions that carry this higher risk include ventricular septal defects, aortic valvular stenosis, tetralogy of Fallot, single ventricle states, prosthetic valves, and postoperative systemic-to-pulmonary shunts. Isolated secundum atrial septal defects carry a much lower risk for bacterial endocarditis because the shunt flow through the atrial septal defect is typically of a much lower velocity.

Clinical Features and Diagnostic Strategies

The early clinical manifestations of bacterial endocarditis may be very nonspecific. The child may simply present with only fever and tachycardia. However, bacterial endocarditis should be suspected in any child with an anatomic cardiac defect who presents with an unexplained fever. This diagnosis must always be considered in any child with a known CHD or an acquired cardiac lesion who presents with any of the condi-
In addition to vigilance for the diagnosis of infective endocarditis—especially in children with CHD—the emergency physician should be aware of the indications for prophylaxis. In 2007 the AHA in conjunction with the AAP and the Infectious Diseases Society of America published revised guidelines for the prevention of infective endocarditis. The changes simplify and greatly narrow the recommendations to provide prophylaxis for only the higher risk patients and procedures (Box 169-15). For those children for whom prophylaxis is recommended, the indications are (1) all dental procedures and (2) any manipulation or perforation of the gingival or oral mucosa. It should be noted that antibiotic prophylaxis for infective endocarditis is no longer recommended for gastrointestinal and genitourinary procedures (Box 169-16). The committee found that it is still reasonable to give prophylaxis for procedures on the respiratory tract, infected skin, or musculoskeletal tissue only for high-risk patients (Table 169-9).

Diagnostic studies to perform in a child with suspected bacterial endocarditis include a complete blood cell count, C-reactive protein (CRP) assessment, measurement of erythrocyte sedimentation rate, three blood cultures, chest radiography, and ECG. Cultures from scrapings of cutaneous emboli can also aid in the diagnosis. Although the definitive diagnostic study is the echocardiogram, it is only 80% sensitive in detecting the nidus of infection on the endocardium or valves. Streptococcus viridans and Staphylococcus aureus are the two most common offending organisms recovered from the blood cultures of children with bacterial endocarditis. Recent studies have shown that in children with CHD, 60% of the cases caused by staphylococcal species are methicillin resistant and were associated with increased risk of mortality.

### Management

Antibiotics should be started immediately after blood culture samples have been obtained. Although the choice of intravenous antibiotics depends on the suspected source of seeding and the child’s immune status, a common recommended regimen includes an aminoglycoside plus a penicillinase-resistant penicillin such as oxacillin. If methicillin-resistant staphylococci are suspected, vancomycin should also be included in the initial empirical antibiotic regimen.

Bacterial endocarditis in the preantibiotic era was nearly always a fatal disease. Although the survival rate in patients with bacterial endocarditis has improved with the initiation of antibiotics, the current mortality rate is still 6 to 14%. Compli-
Myocarditis

Perspective

Myocarditis is an inflammatory condition of the myocardium with various infectious and noninfectious origins. In the United States, the most common cause is viral, with coxsackievirus B and enteroviruses accounting for the majority of cases. Other viral causes include echoviruses, influenza A, influenza B, adenovirus, varicella-zoster virus, Epstein-Barr virus, cytomegalovirus, and hepatitis B virus. Bacterial causes include Corynebacterium diphtheriae, Streptococcus pyogenes, S. aureus, Mycoplasma pneumoniae, Borrelia burgdorferi, and Meningococcus. Noninfectious causes include Kawasaki disease, acute rheumatic fever (ARF), collagen vascular disorders (e.g., systemic lupus erythematosus, rheumatoid arthritis), myocarditis (ARF), systemic lupus erythematosus, attherosclerotic vascular disease, and drug-induced cardiomyopathies.

Clinical Features

Myocarditis usually has a gradual onset with preceding upper respiratory tract infection symptoms. The presenting signs and symptoms of a child with myocarditis depend on the cause of the myocarditis, the age of the patient, and the degree of myocardial inflammation. The key to diagnosing myocarditis in infants and children is to suspect the diagnostic entity in the appropriate clinical setting. In mild cases, the only sign of myocarditis may be tachycardia. Tachycardia that is disproportionate to the degree of fever should alert the clinician to the possibility of myocarditis. Other presenting signs and symptoms include fever, myalgias, fatigue, tachypnea, wheezing, abdominal pain, and chest pain. More severe cases of myocarditis can even present with signs and symptoms of acute CHF and various dysrhythmias. The physical examination may reveal a new murmur, a gallop rhythm, or a pericardial friction rub with muffled heart tones (if the myocarditis is also accompanied by pericarditis).

Diagnostic Strategies and Management

The evaluation and management of the child with myocarditis depend on the suspected cause and the presenting signs and symptoms. Blood cultures and viral titers should be considered in infectious and postinfectious cases. Appropriate antibiotics should be initiated immediately in cases with suspected bacterial origin. The chest radiograph in very mild cases may be normal, but in more advanced cases cardiomegaly will be evident. The ECG findings are usually nonspecific and can include low-voltage, nonspecific ST segment abnormalities, T wave inversions, atrioventricular blocks, and various other dysrhythmias. Creatine phosphokinase-MB, cTnT, CRP, and erythrocyte sedimentation rate may be elevated.

The echocardiogram is an essential component of the workup of any child with suspected myocarditis. The echocardiogram will not only be useful to assess the degree of left ventricular function, but it will also be able to detect any associated pericardial effusion that may accompany the myocarditis. Although an endomyocardial biopsy is rarely required, it is the definitive method to confirm the diagnosis and origin of myocarditis. If the endomyocardial biopsy is performed, it will typically demonstrate a myocardial inflammation with lymphocytic and monocytic infiltrates. The goal of treatment is to maintain adequate cardiac output and to control any associated dysrhythmias. Children who present in CHF may require inotropic support and diuretics. Digoxin and the various pressors must be used very cautiously in children with myocarditis because the inflamed myocardium is very sensitive to the dysrhythmogenesis of these medications. The use of beta-blockers is contraindicated, and the routine use of immunosuppressive agents remains controversial. Although the majority of children with acute viral myocarditis make a full recovery, a few patients will progress to develop dilated cardiomyopathy, which is characterized by dilated ventricles and impaired systolic contractility.

Pericarditis

Perspective

Pericarditis is an inflammatory process within the pericardial sac, which may not be associated with a pericardial effusion. The majority of cases of pericarditis in children are self-limited and follow a benign clinical course. In children, there is normally about 10 to 15 mL of fluid within the pericardial sac. A sudden increase or a large amount of fluid within this pericardial sac can cause a tamponade-induced decrease in stroke volume, which will cause a diminished cardiac output and hypotension.

Although the most common causes of pericarditis include bacterial and viral infections, other causes include ARF, systemic lupus erythematosus, uremia, postpericardiotomy syndrome, leukemia, lymphoma, and tuberculosis. Approximately 30% of pericarditis cases are due to bacteria such as Pneumococcus, S. aureus, Meningococcus, and Haemophilus influenzae. Approximately 30% of the purulent bacterial pericarditis cases occur in children younger than 6 years. Although viral causes are common, a viral pathogen is recovered in only 20 to 30% of these cases. Common viral causes include coxsackieviruses, ECHO viruses, adenovirus, Epstein-Barr virus, and influenza viruses.

Clinical Features

The presenting signs and symptoms of pericarditis depend on the cause of the pericarditis as well as on the amount of fluid that has accumulated within the pericardial sac. Chest pain that varies with position is a common complaint with pericarditis. The chest pain that is classically associated with pericarditis is exacerbated with inspiration and the supine position but relieved when the patient sits up or leans forward. Tachycardia is also a common finding in patients with pericarditis. Other physical examination findings that have been associated with pericarditis include fatigue, tachypnea, neck vein distention, pulsus paradoxus, hepatomegaly, lower extremity edema, and tachyarrhythmias. The cardiac auscultatory findings in a patient with pericarditis can include a harsh-sounding friction rub or diminished or muffled heart sounds, if there is a significant amount of fluid within the pericardial sac. The pericardial friction rub, if present, is best heard when the patient sits up or leans forward. This friction rub of pericarditis can be distinguished from a pleural friction rub by the patient holding his or her breath during auscultation. The friction rub of pericarditis will remain present during breath-holding while the pleural friction rub will no longer be heard while the patient holds the breath.
The chest radiograph in a child with pericarditis may not reveal an enlarged cardiac silhouette, depending on the amount of fluid that has accumulated within the pericardial sac. If there is a large collection of fluid within the pericardial sac, the heart shadow on the chest radiograph will resemble a “water bottle” silhouette. Approximately 50% of pericarditis cases also have an associated pleural effusion.

The classic ECG findings of pericarditis include diffuse ST segment elevation and diffuse T wave inversions in all leads. The classic ECG changes associated with pericarditis evolve through four phases (Fig. 169-13). During the initial phase, there is diffuse ST segment elevation in all leads secondary to subepicardial inflammation; PR segment depression may also be seen. During the second phase, the previously elevated ST segments begin to return to isoelectric baseline and the T wave amplitudes begin to decrease with flattening of the T waves. During the third phase, although the ST segments are now back to isoelectric baseline, the T waves are now inverted. The fourth and final phase demonstrates complete resolution of the ST segment and T wave abnormalities. Diminished ECG voltages in all leads can also occur if there is a significant amount of fluid accumulated within the pericardial sac.

The diagnostic procedure of choice in any patient with suspected pericarditis is the echocardiogram, because this study will confirm both the presence and the amount of accumulated fluid within the pericardial sac. Although echocardiography cannot accurately quantify the exact amount of fluid that has accumulated within the pericardial space, the presence of an anterior and posterior fluid collection is suggestive of a large collection.

**Management**

The management of a child with pericarditis depends on both the suspected cause and the amount of fluid that has accumulated within the pericardial space. An emergency pericardiocentesis will be required in those patients who develop signs of acute cardiac tamponade. Any fluid that is aspirated from the pericardial space should be sent for routine cell counts, Gram's stain, and cultures. Anti-inflammatory agents and appropriate antibiotics should also be initiated based on the suspected cause. Steroids are reserved for refractory cases that are not responsive to the above agents and would be considered only after an infectious etiology is ruled out.

**Kawasaki Disease**

**Perspective**

Kawasaki disease, originally described as mucocutaneous lymph node syndrome by Dr. Tomisaku Kawasaki in 1967, has emerged as a significant cause of acquired cardiac disease in children in the United States. An estimated 3000 to 5000 cases of Kawasaki disease are diagnosed annually.
Diagnostic Criteria for Kawasaki Disease (KD)

I. Fever ≥5 days
II. At least four of the five following physical examination findings:
   1. Bilateral, nonexudative bulbar conjunctival injection (bilateral scleral injection with peribulbar sparing).
   2. Oropharyngeal mucous membrane changes (pharyngeal erythema, red/cracked lips, and a strawberry tongue).
   3. Cervical lymphadenopathy (with at least one node >1.5 cm in diameter).
   4. Peripheral extremity changes (diffuse erythema and swelling of the hands and feet during the acute phase or periangual desquamation during the convalescent phase of the illness). This diffuse palmar erythema seen in KD is in contrast to the discrete macular lesions of various viral illnesses (e.g., measles) that can sometimes be seen on the palms and soles.
   5. A polymorphous generalized rash (nonvesicular and nonbullous). There is no specific rash that is pathognomonic for KD.

In a child with ≥4 criteria, the diagnosis may be made on day 4 of the fever.67

Clinical Features

The key to prevention of the coronary artery complications of Kawasaki disease is first to recognize the clinical signs and symptoms of this disease. In addition to fever, the physical examination of a child with Kawasaki disease may reveal the typical findings as listed in Box 169-17 and illustrated in Fig. 169-14. The classic features of Kawasaki disease may manifest simultaneously or in series over days; a careful history and physical examination may elucidate the need for further testing. In addition, very young children may not have a classic presentation and require further investigation. All children with suspected Kawasaki disease, with either classic or incomplete features, should undergo echocardiography to detect the presence and degree of coronary aneurysm.67

Incomplete Kawasaki Disease

The classic presentation of Kawasaki disease is a clinical diagnosis of four or more of the five criteria in a child who is febrile five or more days. However, these strict criteria may miss a substantial number of children who present with incomplete Kawasaki disease. Any child may have an incomplete presentation, but this is mostly seen in infants less than 6 months old.67

The AHA's Committee on Rheumatic Fever, Endocarditis, and Kawasaki Disease has published consensus guidelines on the approach to incomplete Kawasaki disease.68 The more inclusive criteria recommend that in a child who is febrile 5 days or greater, the presence of two or three criteria should prompt further testing. A CRP of 3 mg/dL or more and/or an erythrocyte sedimentation rate (ESR) of 40 mm/hr or more necessitate further laboratory investigation, such as those listed in Box 169-18. All of these children will also need echocardiography to assess coronary aneurysm, and the recommendation is to treat empirically those whose supplementary laboratory values (see Box 169-18) are positive for systemic inflammation while awaiting echocardiographic confirmation.67

Children with a CRP of less than 3 mg/dL and an ESR of less than 40 mm/hr may be followed daily and reassessed. It is important to note that the committee also added a stipulation that the infant 6 months or younger with fever of 7 or more days should also undergo supplemental laboratory testing, and if any signs of systemic inflammation are found, should have an echocardiogram. This underscores the current limits of diagnosis of Kawasaki disease, as well as the obligation to prevent the disastrous sequelae of aneurysmal development.

Differential Considerations

Measles can mimic Kawasaki disease but is rare in vaccinated children (i.e., a febrile illness with red eyes, a rash, and erythema of the oropharynx). The classic location, distribution, and progression of a measles rash starts on the head and face and progresses caudally. The rash of Kawasaki disease typically begins on the trunk and then spreads to the face and extremities. In contrast, Kawasaki disease can exhibit a polymorphous rash that is nonbullous and nonvesicular.

The palmar lesions of measles are discrete macular lesions (see Fig. 169-14F), whereas the palmar finding in children with Kawasaki disease is diffuse erythema, which may later lead to desquamation (see Fig. 169-14C).

Streptococcal disease, including pharyngitis and scarlet fever, can be confused with Kawasaki disease, but conjunctivitis and swelling of the hands and feet are unusual for streptococcal disease. Other infectious or autoimmune etiologies that may mimic Kawasaki disease include Rocky Mountain spotted fever and leptospirosis, or Stevens-Johnson syndrome and juvenile rheumatoid arthritis.67

As seen above, there are many imitators of Kawasaki disease. Conversely, this systemic vasculitis can affect any organ system, and thus mislead the clinician in diagnosis. For example, Kawasaki disease can present with nausea, vomiting, and abdominal pain in a febrile child, which may be mistaken for a surgical abdomen. In addition, a febrile, irritable child with Kawasaki disease may exhibit a cerebrospinal fluid pleocytosis and be misdiagnosed with viral meningitis. For this reason, Kawasaki disease should be included in the differential diagnosis of any child with several days of fever, rash, and nonpurulent conjunctivitis to avoid the pitfall of early diagnostic closure.

Clinical Course

Kawasaki disease is postulated to be caused by an infectious agent that enters the respiratory tract and initiates an oligoclonal immunoglobulin A response, which activates lymphocytes, cytokines, and proteinases that weaken vessel walls and predispose the entire circulation to aneurysms.68 The main reason to recognize this disease entity in children is to initiate prompt therapies to prevent the cardiac complications of Kawasaki disease, which occur in two phases. Approximately 25% of patients develop mild diffuse myocardial inflammation. This occurs during the acute febrile period and is characterized by...
Chapter 169 / Cardiac Disorders

Albumin ≤3 g/dL
Anemia for age
Platelet count of ≥450,000/mm³
White blood cell (WBC) count ≥15,000 mm³
Elevation of alanine aminotransferase
Sterile pyuria of ≥10 WBCs per high-power field

Figure 169-14. Classic physical examination findings of Kawasaki disease. Note the bilateral nonexudative scleral injections (A) with perilimbic sparing (the thin margin of white sclera around the cornea), red-cracked lips with a strawberry tongue (B), diffuse palmar erythema (C), red soles (D), and the polymorphous exanthem (E). The diffuse palmar erythema of Kawasaki disease (C) is distinct from the palmar findings seen in other viral illnesses such as the discrete macular lesions on the palms in this child with measles (F).

tachycardia, a gallop rhythm, or nonspecific ST-T wave changes. Up to 5% of the children also exhibit some degree of CHF during this acute phase of their illness. This carditis usually resolves when the fever resolves. Pericardial effusions also occur in up to 20 to 40% of cases. Mild mitral and aortic regurgitation is also seen in 1 to 2% of untreated cases on echocardiographic examinations. This phase of the disease is mild and self-resolving. Therapy during this phase of the illness is primarily supportive.

The second phase of the disease involves coronary artery dilation, which usually peaks 2 to 4 weeks from the onset of the illness and is seen in 15 to 25% of the untreated patients with Kawasaki disease. Without the appropriate treatment, 15 to 20% of children with Kawasaki disease go on to develop
coronary aneurysms within 1 to 3 weeks from the onset of their illness. These coronary aneurysms can then lead to myocardial infarction, thrombosis, rupture, and a variety of ischemia-induced dysrhythmias. Significant risk factors for coronary aneurysmal formation include male gender, age younger than 1 year or greater than 8 years, a prolonged febrile period greater than 10 to 14 days, early myocarditis, anemia (Hgb < 10 g/dL), white blood cell count greater than 30,000, an increased band count, elevated ESR, elevated CRP level, low serum albumin levels, and aneurysms involving the renal, axillary, or iliac arteries and giant coronary aneurysms (>8 mm in diameter). Death from Kawasaki disease is primarily due to myocardial infarction secondary to coronary artery occlusion. Giant coronary artery aneurysmal rupture is rare. Although most of the fatalities that occur with Kawasaki disease occur within 6 weeks from the onset of the illness, sudden death can also occur many years after the illness. Prompt recognition and treatment have decreased this mortality rate from 2% to less than 0.01%.66

Management
The main goal of treatment during the acute febrile phase of Kawasaki disease is to provide supportive care and to decrease the inflammation of the myocardium and coronary arteries. The two major components of treatment include intravenous immunoglobulin (IVIG) infusion and high-dose aspirin therapy, which together have an additive effect. This combination of IVIG and high-dose aspirin, when initiated within 10 days from the onset of the illness, can substantially decrease the progression to coronary artery dilation and aneurysm formation as compared with aspirin therapy alone and results in a more rapid resolution of fever and the other indicators of acute inflammation.66 However, despite prompt treatment with IVIG and high-dose aspirin, 2 to 4% of the children still develop coronary artery abnormalities.66

The current IVIG regimen involves an infusion of 2 g/kg over 10 to 12 hours. Side effects of IVIG include hypotension, nausea, vomiting, and seizures. Close cardiac monitoring during the IVIG infusion is mandatory. The 5 to 10% of children who receive IVIG who experience a persistent or recurrent fever after the initial dose of IVIG may be given a second infusion at the same dose. Approximately two thirds of those children who fail to respond to the initial dose of IVIG will improve with the second infusion.

Aspirin is initiated at 80 to 100 mg/kg/day orally divided into an every-6-hour dosing regimen until the child is afebrile for 48 to 72 hours (or longer). This dose is then decreased to 3 to 5 mg/kg orally each day until the laboratory study results return to normal, which typically occurs 6 to 8 weeks after the onset of the disease. Aspirin therapy is continued beyond this period only in those children in whom coronary artery abnormalities are present. Ibuprofen can antagonize the antiplatelet effects of aspirin and should be avoided during treatment.67

The use of corticosteroids as primary treatment has not been well established. A recent multicenter, randomized, double-blind study to determine the efficacy of the addition of methylprednisolone to initial conventional therapy showed no difference in clinical outcome, including dimensions of coronary artery aneurysms, length of hospital stay, and rate of retreatment with IVIG.70 The current recommendations include corticosteroids for refractory cases of Kawasaki disease, in which children are continued on high-dose aspirin, a second dose of IVIG is administered, and corticosteroids are added to decrease the risk of coronary artery aneurysm.67 Other complications such as coronary aneurysmal thrombosis likewise have limited data to guide management. Therapeutic options include streptokinase, tissue-type plasminogen activator, and interventional cardiac catheterization.67

The follow-up of children with Kawasaki disease depends on the degree and presence of carditis and coronary artery abnormalities detected on the initial echocardiogram. Other imaging modalities used to follow aneurysmal parameters include electron-beam computed tomography, coronary magnetic resonance angiography, and multislice spiral computed tomography.67 Those children with more severe cardiac abnormalities require very close follow-up by a cardiologist who is experienced in managing the cardiac complications of Kawasaki disease. Overall, prompt diagnosis and appropriate therapies can prevent coronary aneurysm formation in up to 95% of the cases as well as rapid symptomatic improvement in up to 90% of the cases.72

Acute Rheumatic Fever
Perspective
Acute rheumatic fever is the result of a delayed immune reaction of a group A streptococcal infection. ARF is one of the most common causes of acquired heart disease in children. In the United States, ARF most commonly occurs in children 5 to 15 years of age and has an attack rate of 0.3% in children with an untreated streptococcal infection. Although this disease affects multiple organ systems, carditis is the most serious complication.

Clinical Features and Diagnostic Considerations
The diagnosis of ARF is based on the Jones criteria (Box 169-19). In addition to the Jones criteria, there must also be evidence of an antecedent streptococcal infection, which can be documented with either a positive throat culture, a positive rapid streptococcal antigen test finding, or an elevated anti-streptolysin O titer. The streptozyme test is not as reliable and therefore should not be used as a definitive test for evidence of an antecedent group A streptococcal infection.73 The diag-

---

**BOX 169-19 JONES CRITERIA FOR THE DIAGNOSIS OF ACUTE RHEUMATIC FEVER (ARF)**

The diagnosis of ARF is based on the documentation of an antecedent streptococcal infection and either two major criteria or one major criterion + two minor criteria.

**Major criteria**
- Carditis
- Migratory polyarthritis
- Erythema marginatum
- Subcutaneous nodules
- Chorea

**Minor criteria**
- Clinical findings
  - Fever
  - Arthralgia
- Laboratory findings
  - Elevated C-reactive protein or erythrocyte sedimentation rate
  - Prolonged PR interval
- Supporting evidence of an antecedent group A streptococcal infection with either:
  - A positive throat culture or a rapid streptococcal antigen test
  - An elevated anti-streptolysin O titer
nosis of ARF is made in a patient with a documented antecedent streptococcal infection who exhibits either two major criteria or one major plus two minor criteria. The most common presenting major criterion is the migratory polyarthritis, which commonly involves the larger joints of the extremities as well as the smaller tarsal joints in the foot and the smaller carpal joints in the hand. The carditis of ARF most commonly involves valvulitis of the mitral and aortic valves, which clinically manifests as occult mitral or aortic insufficiency. The murmur of mitral insufficiency is characterized as a holosystolic murmur best heard over the apex with radiation to the axilla. The murmur of aortic insufficiency is characterized as a diastolic murmur that is best heard over the base of the heart. Innocent murmurs that are normally exacerbated with fever can be mistaken for the murmurs of mitral or aortic insufficiency. The other cardiac manifestations of ARF include CHF, pericarditis, and various degrees of heart blocks. The two dermatologic major criteria (erythema marginatum and subcutaneous nodules) and chorea occur less commonly than the migratory polyarthritis and carditis. Chorea may occur as the only manifestation of ARF. If arthritis is used as a major component, arthralgia cannot be used as a minor component to make the diagnosis. Likewise, if carditis is used as a major component, then a prolonged PR interval cannot be used as a minor component.

In addition to the ECG, CRP level, ESR, and documentation of an antecedent streptococcal infection, the diagnostic workup of ARF should also include a chest radiograph as well as an echocardiogram to evaluate the degree of cardiac involvement.

Differential Considerations

The differential diagnosis of ARF includes myocarditis, bacterial endocarditis, Lyme disease, systemic lupus erythematosus, juvenile rheumatoid arthritis, serum sickness, and septic arthritis.

Management

The acute management of ARF should first focus on stabilizing and treating any of the symptomatic cardiac manifestations of the illness, such as CHF or tamponade due to a pericardial effusion. Additional goals in ARF management include appropriate antibiotic therapy to eradicate the streptococcal infection, bedrest, and anti-inflammatory agents for the arthritis. The use of steroids in the treatment of carditis should only be employed under direction of a cardiologist. Another important aspect in the management of ARF is the prevention of recurrent attacks through the prophylactic use of penicillin, which can be given as monthly injections of 1.2 million units of benzathine penicillin G. Alternative prophylactic regimens include oral penicillin administered twice daily, or for penicillin-allergic patients, twice daily oral erythromycin. This prophylaxis with penicillin or erythromycin is required until 18 years of age at the minimum but can be continued for life, depending on the degree of cardiac involvement and the risk for recurrence.

Cardiac Causes of Sudden Death in Young Athletes

Perspective

The most common cause of sudden, unexplained death in athletes is various cardiac conditions, with only 15% of the cases stemming from noncardiovascular causes (Box 169-20).

The most common cardiovascular cause of sudden death in the athlete is hypertrophic cardiomyopathy, which accounts for up to 36% of the cardiovascular-related cases.

Specific Disorders

Congenital Coronary Artery Anomalies. An additional 24% of the cases of sudden death are due to various anomalies of the coronary arteries. Congenital coronary artery anomalies are difficult to detect from a clinical standpoint, but 37% of those individuals who died from congenital coronary artery anomalies did exhibit previous symptoms of exercise-induced syncope or chest pain. The exact pathophysiologic mechanism of sudden death in individuals with congenital coronary anomalies is unknown. Although there are a variety of congenital coronary artery anomalies, the most common potentially lethal lesion is the anomalous left coronary artery in which the left main and right coronary arteries both arise from the right sinus of Valsalva. Individuals with this particular anomaly have a 46% incidence of sudden death, with more than 85% of the known cases of sudden death occurring during exercise. Congenital coronary artery hypoplasia is another uncommon cause of exercise-induced sudden death. Any athlete with exertional syncope or chest pain should be evaluated by a cardiologist for the possibility of congenital coronary artery anomalies. If an anomaly is detected and surgically corrected, the athlete may resume full activity and participation in competitive sports.

Marfan’s Syndrome. Individuals with Marfan’s syndrome should be evaluated for potential cardiac abnormalities before being allowed to participate in competitive sports. Clinical manifestations of the disease include tall, slender habitus, striae atrophicae of the skin (multiple stretch marks on skin), disproportionately long extremities as compared to the trunk, scoliosis, pectus excavatum or carinatum, and dislocated lenses of the eye. Approximately 50% of patients with Marfan’s syndrome have cardiac manifestations such as mitral valve prolapse or aortic dilation. The most serious cardiac complication of Marfan’s syndrome is the progressive dilation of the aorta with the potential risk of aortic rupture, which most commonly involves the descending portion of the aorta. Therefore, patients with Marfan’s syndrome should be prohibited from participation in contact sports. Those individuals who are known to have aortic dilation should also be prohibited from participation in any competitive sports regardless of the degree of contact involved. All patients with Marfan’s syndrome with or without cardiac involvement on their initial evaluation should be followed by a cardiologist with serial imaging studies of their aorta using echocardiography, magnetic resonance imaging, or computed tomography.
Hypertrophic Cardiomyopathy

Perspective. Although the nonobstructive form of hypertrophic cardiomyopathy is an uncommon cardiac malformation that occurs in only 0.2% of the general population, it is the single most common cardiac cause of sudden death in the young athlete. 77-79 Hypertrophic cardiomyopathy is a familial disease that is inherited in an autosomal dominant fashion with variable penetrance. The hypertrophy of the left ventricle in this condition is idiopathic in nature and not due to chronic pressure overload conditions such as systemic hypertension or aortic stenosis. The systolic left ventricular contractile function is vigorous but the thickened muscle of the left ventricle is stiff, resulting in impaired ventricular relaxation and high diastolic filling pressures. 80

Sudden death in previously asymptomatic individuals with hypertrophic cardiomyopathy occurs during moderate or severe physical exertion. The proposed pathophysiologic mechanisms of sudden death during exertion in these individuals is thought to be due to a transient decrease of blood flow out through the aorta or to dysrhythmias secondary to the hypertrophied ventricular myocardium.

Clinical Features. Some individuals with hypertrophic cardiomyopathy have experienced previous “warning” episodes of chest pain, dyspnea, syncope, or palpitations during vigorous activities. A family history of sudden unexplained death in young adults should also alert the clinician to the possibility of hypertrophic cardiomyopathy. The majority of young athletes who die from this condition have the nonobstructive form of hypertrophic cardiomyopathy, and the classic loud systolic ejection murmur that is present with the obstructive form is not heard during the routine presports physical examinations. 81 Therefore, the standard presports screening physical examination may fail to detect the presence of nonobstructive hypertrophic cardiomyopathy in young athletes. If a systolic murmur along the lower left sternal border is heard on the routine screening physical examination of a young athlete, a Valsalva maneuver may help to differentiate the murmur of aortic stenosis from the systolic murmurs associated with the obstructive form of hypertrophic cardiomyopathy. During the Valsalva maneuver, the venous blood return to the heart is decreased, which in turn transiently reduces the left ventricular size. The transient reduction in the size of the left ventricle will increase the degree of obstruction and thus cause an increase in the intensity of the systolic murmur heard with the obstructive form of hypertrophic cardiomyopathy. In contrast to this, the systolic murmur of aortic stenosis will decrease in intensity during a Valsalva maneuver due to the transient reduction of blood flow through the stenotic aortic valve.

Individuals who are suspected of having hypertrophic cardiomyopathy based on the above-mentioned exertional symptoms, a positive family history, or both should be referred to a cardiologist for a more extensive workup.

Diagnostic Studies. The ECG findings in individuals with hypertrophic cardiomyopathy typically reveal various degrees of left ventricular hypertrophy and left atrial enlargement. Other ECG findings include prominent Q waves in the inferolateral leads or diffuse T wave inversions. The most accurate study to make the diagnosis of hypertrophic cardiomyopathy is the echocardiogram, which will demonstrate various degrees of left ventricular hypertrophy most commonly involving the ventricular septum in up to 90% of the cases. 81 Those patients who have echocardiographic evidence of hypertrophic cardiomyopathy should be followed with serial echocardiographic examinations to monitor the progression of their condition.

Management. Although beta-blockers have been used in patients with hypertrophic cardiomyopathy, they have not been shown to prevent sudden death in these patients. The use of digoxin is contraindicated in patients with hypertrophic cardiomyopathy because its positive inotropic effect may worsen the left ventricular outflow obstruction. Sudden death in these patients with hypertrophic cardiomyopathy is thought to be due to exertion-induced ventricular fibrillation or pulseless ventricular tachycardia. Therefore, the current recommendation is that all individuals who are diagnosed with hypertrophic cardiomyopathy, as well as those individuals with an equivocal diagnosis of hypertrophic cardiomyopathy, should not participate in vigorous activities and competitive sports.

Prolonged QT Syndrome

Perspective. In 1957, Jervell and Lange-Nielsen first described the association of recurrent syncope, sudden death, and long QT interval in a series of deaf patients. Later, in 1963, Romano reported a similar association of symptoms with long QT intervals in patients with normal hearing. Both the Jervell-Lange-Nielsen syndrome and the Romano-Ward syndrome are inherited disorders with variable penetrance, characterized by a prolonged QT interval that has been associated with sudden death. The corrected QT interval (QTc) in normal individuals should not exceed 0.44 seconds in children or 0.42 seconds in adolescents. Individuals with QTc intervals greater than 0.55 seconds have a higher risk of sudden death. Prolongation of the QT interval predisposes the individual to ventricular tachycardia, torsades de pointes, and ventricular fibrillation, which is often initiated by a premature ventricular contraction occurring during the prolonged repolarization phase. In addition to the inherited syndromes of prolonged QT intervals, other causes of prolonged QT intervals include hypocalcemia, hypokalemia, hypomagnesemia, myocarditis, and medications (e.g., procainamide, erythromycin, cyclic antidepressants, phenothiazines, quinidine, organophosphates).

Clinical Features. Symptoms in the young athlete that are suggestive of QT prolongation include exercise-induced palpitations, chest pains, syncope, dizziness, or atypical seizures. The young athlete who develops any of these symptoms should be evaluated by a cardiologist, especially if the family history is positive for sudden unexplained death, cardiac problems, syncope, or deafness. Any young athlete who has been diagnosed with a prolonged QT syndrome should be prohibited from participation in competitive sports and vigorous activities. The growing popularity and presence of AEDs in public places and at sporting events can potentially save the lives of those athletes who suddenly collapse due to an underlying prolonged QT syndrome–induced nonperfusing ventricular dysrhythmia.

Management. Treatment of a prolonged QT interval depends on the cause. Correction of any underlying metabolic disorder and discontinuing a medication that induced the prolongation of the QT interval are the easiest conditions to correct. Magnesium sulfate is the drug of choice in the treatment of torsades de pointes. Antidysrhythmic agents that also can prolong the QT interval, such as procainamide and amiodarone, should be avoided. Therefore, the safest medication to use in a patient with prolonged QT interval–induced ventricular tachycardia or fibrillation is lidocaine. Beta-blockers have been used to prevent sudden ventricular dysrhythmias in those patients with the familial forms of QT prolongation. Adjunctive treatment in these selected patients also includes the insertion of pacemakers or internal defibrillators.

Commotio Cordis. The phenomenon of commotio cordis occurs when an object such as a baseball strikes the chest and produces sudden death. This phenomenon most commonly occurs in children between 5 and 15 years of age with known predisposing cardiac conditions. 75,82 Although commotio cordis most commonly occurs in baseball, it has also been reported to occur in ice hockey, lacrosse, softball, and fist fights. 89 In a
few cases in which the cardiac rhythm was documented after the blunt trauma to the chest, the most common rhythm documented was ventricular fibrillation. The majority of patients who sustain commotio cordis do not survive, especially if they are not rapidly treated with defibrillation. If an AED is not immediately available and the patient is completely unresponsive with no pulse after sustaining a direct blow to the chest, some practitioners have proposed that performing chest thumps during cardiopulmonary resuscitation may be of some benefit under this particular circumstance.

## KEY CONCEPTS

- The possibility of a congenital heart defect should be considered in an infant who presents with central cyanosis that does not respond to 100% supplemental oxygen (hyperoxia challenge).
- Neonates with ductal-dependent cardiac lesions typically present within the first 2 to 3 weeks of life with either acute cyanosis or shock. Initiation of a PGE1 infusion (0.05–0.1 µg/kg/min) will be lifesaving in these neonates.
- Treatment of a hypoxic tet spell first includes placing the infant in the knee-to-chest position and providing supplemental oxygen. Sedative agents can be used to decrease the infant’s hyperpnea. Various medications can be used as adjunctive treatment to increase the SVR and thereby decrease the degree of right-to-left shunting across the ventricular septal defect.
- Prompt recognition of the clinical findings and symptoms of Kawasaki disease along with the rapid initiation of high-dose aspirin and IVIG infusion can prevent the formation of coronary aneurysms.
- Acute bacterial endocarditis should always be considered in a child with a known congenital heart defect or an acquired cardiac defect who presents with a fever of unknown origin, the development of acute neurologic deficits, new-onset microscopic hematuria, myalgias, splenomegaly, petechiae, or other signs of systemic embolization.
- Oxygen, diuretics (furosemide), and inotropic agents (digoxin) are the mainstay of treatment for infants and children who present with CHF.
- If vagal maneuvers fail to convert stable paroxysmal supraventricular tachycardia in children, rapid adenosine administration (0.1 mg/kg for the first dose followed by 0.2 mg/kg on repeat doses) is the treatment of choice. Verapamil should be avoided in children younger than 1 year due to its profound hypotensive effects.
- One should consider the use of lidocaine instead of amiodarone in cases of ventricular fibrillation or ventricular tachycardia due to medications (e.g., cyclic antidepressants) or toxins that prolong the QT interval.
- Young athletes with a positive family history of sudden unexplained death or exertion-induced symptoms such as chest pain, dyspnea, palpitations, or syncope should be evaluated by a cardiologist prior to their resumption of vigorous activity.
- The increased presence of AEDs in public places and at sporting events can potentially save the lives of more young athletes who suddenly collapse secondary to hypertrophic cardiomyopathy, prolonged QT syndromes, and commotio cordis.

NEONATAL JAUNDICE

Perspective
Many infants become jaundiced during the newborn period, most often as a result of a benign, self-limited process. Physiologic jaundice of the newborn is the most common cause of neonatal jaundice and occurs in approximately 60% of normal newborns during the first week of life. Breast milk jaundice is the second most common cause of jaundice in the newborn period.

Principles of Disease
Bilirubin is formed by the breakdown of heme-containing proteins, primarily hemoglobin. Heme protoporphyrin is sequentially degraded into biliverdin and unconjugated bilirubin. Unconjugated bilirubin binds to albumin in the blood and is carried to the liver, where it is conjugated by glucuronyl transferase and excreted into bile. Jaundice may be caused by increased amounts of either unconjugated or conjugated bilirubin and becomes clinically apparent when the total bilirubin level reaches approximately 5 mg/dL. Conjugated hyperbilirubinemia occurs when the direct-reacting portion exceeds 2 mg/dL or is greater than 20% of the total.

The exact pathogenetic mechanism of breast milk jaundice is uncertain. Breast milk jaundice may be hormonally mediated or related to intestinal excretion and resorption of bile. Jaundice may be caused by increased amounts of either unconjugated or conjugated bilirubin and becomes clinically apparent when the total bilirubin level reaches approximately 5 mg/dL. Conjugated hyperbilirubinemia occurs when the direct-reacting portion exceeds 2 mg/dL or is greater than 20% of the total.

The exact pathogenetic mechanism of breast milk jaundice is uncertain. Breast milk jaundice may be hormonally mediated or related to intestinal excretion and resorption of bile. Jaundice may be caused by increased amounts of either unconjugated or conjugated bilirubin and becomes clinically apparent when the total bilirubin level reaches approximately 5 mg/dL. Conjugated hyperbilirubinemia occurs when the direct-reacting portion exceeds 2 mg/dL or is greater than 20% of the total.

Clinical Features
Physiologic jaundice of the newborn is the most common cause of neonatal jaundice and occurs in approximately 60% of normal newborns during the first week of life. Affected infants are born with normal bilirubin levels that gradually increase to a peak level of 6 mg/dL on the third day of life and then decline to normal within 2 weeks. Breast milk jaundice is the next most common cause of hyperbilirubinemia in newborns. Affected infants exhibit the same gradual increase seen with physiologic jaundice. Levels continue to increase, however, and reach a higher peak level at 10 days to 3 weeks of life. Elevated levels may persist for 3 to 10 weeks and then gradually subside.

Toxic levels of bilirubin (greater than 20 mg/dL and dependent on age) may be associated with neurotoxicity, encephalopathy, and the development of kernicterus. Kernicterus is characterized by yellow staining in areas of the brain, including the basal ganglia. Clinical manifestations begin with poor feeding and lethargy and may progress to muscular rigidity, opisthotonos, seizures, and death. Survivors may have residual problems with coordination, hearing, and learning disabilities. The cornerstones of therapy are phototherapy and exchange transfusion.

Diagnostic Strategies
Although physiologic jaundice of the newborn and breast milk jaundice are most common, it is important to identify truly pathologic causes of jaundice. Initial testing requires determination of fractionated levels of total and direct bilirubin. Box 170-1 lists indications for workup in infants presenting with hyperbilirubinemia. Conjugated (direct) hyperbilirubinemia is always pathologic. In such cases, a minimal workup should include a complete blood count (CBC) with peripheral smear and a Coombs’ test for immune-mediated major blood group incompatibility. Ill-appearing infants also require finger-stick blood glucose measurement, electrolyte panel, urine assay for reducing substances, and serum ammonia determination to rule out inborn errors of metabolism.

Differential Considerations
Birth history should be obtained to elicit any history of trauma, because large, resolving hematomas can result in jaundice. Family history should focus on identifying siblings or other relatives with a history of jaundice or genetic or metabolic disorders and any unexplained infant deaths. Tables 170-1 and 170-2 present full lists of differential considerations for jaundiced infants and children, respectively.

Infants with direct hyperbilirubinemia represent a special subset of patients. All infants with direct hyperbilirubinemia require hospital admission and evaluation for the cause of the jaundice based on history and presenting signs and symptoms. This evaluation may include any or all of the following: sepsis...

Box 170-1  Indications for Workup in Jaundiced Infants

Jaundice appearing within 24 hours of birth
Elevated direct (conjugated) bilirubin level
Rapidly rising total serum bilirubin unexplained by history or physical examination
Total serum bilirubin approaching exchange level or not responding to phototherapy
Jaundice persisting beyond age 3 weeks
Sick-appearing infant

workup, TORCHS (toxoplasmosis, other infections, rubella, cytomegalovirus, herpes, syphilis) titers, basic metabolic studies, α1-antitrypsin, sweat test for cystic fibrosis, ultrasound studies, radioisotopes (hepato-iminodiacetic acid [HIDA]/disopropyl iminodiacetic acid [DISIDA]) scan, and liver biopsy. In children, hemolytic anemia, infection, and drugs are the most common causes of jaundice. The history should focus on travel, exposures, medications, and associated signs and symptoms such as fever, malaise, and weight loss. Gentle palpation of the liver is useful to estimate size, firmness, and tenderness and to distinguish hepatomegaly from liver inflammation.

Management

Treatment of infants with hyperbilirubinemia centers on the prevention of kernicterus. Guidelines for using phototherapy and exchange transfusion have been recommended by the American Academy of Pediatrics (Fig. 170-1). Feeding should be continued to the extent possible because oral intake stimulates enterohepatic circulation and decreases bilirubin levels. Unless the infant is severely jaundiced, breast-feeding can be continued and supplemented with formula as needed. Infants
Figure 170-1. A, Guidelines for exchange transfusion in infants of 35 or more weeks' gestation. Note that these suggested levels represent a consensus but are based on limited evidence, and the levels shown are approximations. During birth hospitalization, exchange transfusion is recommended if the total serum bilirubin (TSB) rises to these levels despite intensive phototherapy. For rehospitalized infants, if the TSB level is above the exchange level, repeat TSB measurement every 2 to 3 hours and consider exchange if the TSB remains above the levels indicated after intensive phototherapy for 6 hours. - The dashed lines for the first 24 hours indicate uncertainty due to a wide range of clinical circumstances and a range of responses to phototherapy.
- Immediate exchange transfusion is recommended if infant shows signs of acute bilirubin encephalopathy (hypertonia, arching, retrocollis, opisthotonos, fever, high-pitched cry) or if TSB is 5 mg/dL (85 mmol/L) above these lines.
- Risk factors = isoimmune hemolytic disease, G6PD deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis.
- Measure serum albumin and calculate B/A ratio (see legend).
- Use total bilirubin. Do not subtract direct reacting or conjugated bilirubin.
- If infant is well and 35–37 6/7 wk (median risk), can individualize TSB levels for exchange based on actual gestational age.
who are premature or who have significant comorbidity require treatment at lower levels. Phototherapy often is now readily available on an outpatient basis.

Disposition
In general, infants with bilirubin levels greater than 18 to 20 mg/dL require hospital admission and phototherapy. All infants with direct hyperbilirubinemia require admission and workup.

HYPERTROPHIC PYLORIC STENOSIS

Perspective
Hypertrophic pyloric stenosis is the most common cause of infantile gastrointestinal (GI) obstruction beyond the first month of life. This condition occurs in 1 of every 250 live births. Boys are affected at four times the rate of girls. Hypertrophic pyloric stenosis tends to run in families; however, the exact pattern of inheritance is unclear. The incidence rate is 1 in 14 if the father was affected; the rate is even higher if the mother was affected. Whites are affected more often than African Americans, and the disease is rare in Asian Americans.

Principles of Disease
Infants are born with a normal pylorus, which undergoes hypertrophy only as time progresses. The exact etiology is unknown. As the pylorus continues to hypertrophy, there is progressive gastric outlet obstruction. As vomiting continues, the infant loses hydrogen and chloride ions through emesis of gastric juices. As this metabolic derangement worsens, the kidney attempts to retain hydrogen ions in exchange for potassium, resulting in a hypochloremic, hypokalemic metabolic alkalosis.

Clinical Features
Infants classically present at 2 to 6 weeks old with gradually progressive emesis that becomes projectile and remains nonbilious. Infants remain vigorous with a ravenous appetite. They rapidly finish an entire feeding, only to regurgitate the entire volume in a projectile fashion. In the later stages of the disease, children may exhibit visible waves of abdominal peristalsis in response to intense contractions against an obstruction. Children in the later stages of disease may exhibit marasmus—protein-calorie malnutrition—as a result of impaired nutrient absorption.

Diagnostic Strategies
Children may have a palpable pylorus, commonly referred to as an “olive” in the right epigastrium, on abdominal examination. Placing a nasogastric tube and emptying the stomach or placing the infant in the prone position often facilitates palpation. Hypertrophic pyloric stenosis may be confirmed by ultrasoundography or upper GI series. Ultrasonography is the

**Differential Considerations**

Etiologic possibilities vary depending on whether the course of vomiting has been sudden in onset, gradually progressive, or chronic. Details such as the frequency and volume of emesis also are important because they may have important implications regarding the severity of disease and the potential risk for dehydration or electrolyte disturbance. In infants, other major considerations in the differential diagnosis include gastroesophageal reflux and malrotation. The age of the child and the timing of vomiting provide important clues to the etiology. Reflux classically begins early in life, usually shortly after birth, and remains relatively constant. With pyloric stenosis, vomiting does not begin until 2 to 3 weeks of age and then becomes increasingly severe and projectile; the emesis is rarely if ever bilious. In neonates, bilious vomiting requires careful consideration to rule out the possibility of malrotation with volvulus.

Many causes of vomiting do not have a true GI origin, including sepsis, increased intracranial pressure, middle ear disturbances, urinary tract infections, inborn errors of metabolism, pain, medications, and drug intoxications. Differential considerations for vomiting in children vary by age (Table 170-3).

**Management**

Treatment consists of fluid and electrolyte replacement and surgical consultation. Fluid resuscitation should begin with a 20 mL/kg bolus of normal saline, followed by additional boluses as necessary to treat signs of shock. When the patient is stable and shows no signs of shock, 5% dextrose and half-normal saline at 1.5 to 2 times maintenance may be administered. Potassium supplementation is often necessary. Hypertrophic pyloric stenosis is a chronic, progressive disease, not an acute ischemic process. Confirmatory radiographic diagnosis with ultrasonography may be done on a semi-urgent basis as symptoms warrant. Pediatric surgical consultation is mandatory, although usually not emergent. The definitive corrective surgical procedure is the Ramsteadt pyloromyotomy, which has an excellent track record of safety. More recently, laparoscopic pyloromyotomy has gained increasing acceptance as being safe and effective. Associated mortality is rare.

**Disposition**

Most children probably are best managed with hospital admission for rehydration and correction of electrolyte abnormalities, with imaging and surgical consultation done on a semi-elective basis.

**MALROTATION WITH MIDGUT VOLVULUS**

**Perspective**

Malrotation occurs in 1 in 500 live births and has a male predominance by at least 2:1. Among infants with malrotation, volvulus eventually will develop in approximately 75%, and 75% of these infants present within the first month of life. Overall, 90% of patients present within the first year of life, although cases of adult midgut volvulus have been reported. Bilious emesis is the hallmark presentation and is seen in greater than 75% of cases. Malrotation with volvulus carries a mortality rate of 3 to 15%.

**Principles of Disease**

During embryologic development, the GI tract rotates around the superior mesenteric artery. As it completes the rotation, the duodenum forms a C-loop and is fixed to the retroperitoneum in the left upper quadrant at the ligament of Treitz. The cecum becomes similarly fixed in the right lower quadrant. The duodenum and cecum normally come to lie widely separated and loosely connected by a broad-based mesentery. They are fixed firmly in position by peritoneal attachments called Ladd's bands. In cases of malrotation, the duodenum and the cecum do not rotate completely but end up in close proximity to each other, suspended in the midgut region by their vascular attachment containing the superior mesenteric artery. This unusually close proximity of the intervening mesentery results in a short stalk of mesentery that easily twists on itself, resulting in obstruction of the distal duodenum and compression of the superior mesenteric artery. Vascular compression results in ischemia of the bowel and, if not rapidly reversed, necrosis of the bowel wall in 1 to 2 hours. Twisting of the pedicle also results in various degrees of obstruction secondary to Ladd’s bands that are malpositioned and straddling the duodenum.

Bilious emesis is the hallmark presentation and occurs as a result of severe obstruction. Any pigmented staining of the vomitus suggests the presence of bile. When initially produced, bile is bright yellow and turns green only with time and oxidative exposures. Differential coloring of bile-stained emesis, yellow versus green, is not predictive of surgical pathology.

Clinical Features

Infants classically present with sudden-onset bilious emesis and abdominal distention. The obstruction may be relatively high, however; consequently, a distended abdomen may not always be present. Infants usually appear quite ill and may present in shock. Infants also may present with a history of intermittent, relatively mild episodes of emesis that suddenly become more intense. Although bilious emesis in a neonate always suggests the possibility of acute obstruction and volvulus, presenting manifestations in children may be nonspecific, such as abdominal distention or an ill appearance.

Diagnostic Strategies

Diagnostic strategies may include obtaining a plain film of the abdomen, an upper GI series, or a computed tomography (CT) scan of the abdomen. Findings on plain abdominal films may include air-fluid levels suggesting obstruction, dilated loops overlying the liver, and a paucity of small bowel gas distally (Fig. 170-3). In addition, a “double-bubble sign” may be present, representing a dilated stomach and obstructed proximal duodenum. Three different conditions are associated with this finding on plain abdominal films. The classic double bubble represents a dilated stomach and obstructed proximal duodenum, as noted, and is seen with duodenal atresia and malrotation with midgut volvulus. Duodenal atresia is limited to the newborn nursery and manifests within 24 hours of life.

Malrotation with midgut volvulus typically manifests with bilious vomiting within the first month of life. The modified double-bubble sign seen with hypertrophic pyloric stenosis represents a dilated body of the stomach and pylorus and is associated with nonbilious emesis.

The diagnostic procedure of choice to determine midgut volvulus is the upper GI series, which reveals abnormal position of the duodenal C-loop (Fig. 170-4) and small bowel with a characteristic corkscrew appearance (Fig. 170-5). An ultrasound scan may be obtained because of abdominal pain and may reveal abnormal positioning of the duodenal C-loop and superior mesenteric artery. The place of ultrasonography in the evaluation of children with midgut volvulus has yet to be determined, however.

Differential Considerations

Vomiting in childhood is common and occurs across a wide spectrum of illnesses (see Table 170-3). Causes vary depending on the age of the child and whether the course of vomiting has been sudden in onset, gradually progressive, or chronic. Gastroesophageal reflux classically begins early in life, usually shortly after birth, and remains relatively constant. With pyloric stenosis, vomiting does not begin until the age of 2 to 3 weeks and then becomes increasingly severe and projectile. Acute obstruction causes sudden-onset vomiting, which may be bilious. In a neonate, bilious vomiting requires careful consideration to rule out the possibility of malrotation.

■ Special Populations / SECTION ONE • The Pediatric Patient

Section One
• The Pediatric Patient

Figure 170-3. Upright abdominal radiograph obtained in an infant with bilious vomiting illustrates dilated loops of small bowel and a paucity of bowel gas distally, consistent with proximal obstruction secondary to malrotation with midgut volvulus. (Courtesy of Mark A. Hostetler, MD.)

Figure 170-4. Upper gastrointestinal film, obtained in the same infant as in Figure 170-3, reveals abnormal positioning of the duodenal C-loop to the right of the spinal column, consistent with malrotation. (Courtesy of Mark A. Hostetler, MD.)

Figure 170-5. Another spot film from the upper gastrointestinal series obtained in the infant in Figure 170-3. This radiograph shows the characteristic corkscrew appearance seen on small bowel follow-through in patients with malrotation. (Courtesy of Mark A. Hostetler, MD.)

with volvulus. Necrotizing enterocolitis (NEC) is another consideration because this life-threatening disease also manifests with obstructive signs and symptoms, including bilious emesis and abdominal distention. Whereas malrotation usually is associated with a paucity of small bowel air on plain films, NEC is characterized radiographically by diffusely dilated loops of small bowel. In addition, the presence of pneumatosis intestinalis is diagnostic of NEC but is not a feature of malrotation.

Management

Infants with bilious emesis of sudden onset who appear ill or have a distended abdomen require emergency consultation with a pediatric surgeon. Intravenous access should be obtained and laboratory studies sent for CBC, electrolytes, and liver function tests. Repeated fluid boluses of normal saline, 20 mL/kg, are necessary until adequate circulation has been obtained. A finger-stick sample for blood glucose determination and specimens for blood and urine cultures should be obtained. A nasogastric or orogastric tube should be placed. After consultation with a pediatric surgeon, an upper GI series may be needed emergently. Ill-appearing infants require broad-spectrum, triple-antibiotic coverage with ampicillin, gentamicin, and either clindamycin or metronidazole. Time is of the essence in the evaluation and operative management of these patients. Rapid pediatric surgical consultation should be obtained in any neonate or infant with bilious vomiting even before obtaining diagnostic studies, especially infants who are ill-appearing. In contrast with hypertrophic pyloric stenosis, in which surgery does not need to be immediate, operative intervention must be rapid to save the bowel from necrosis.

Disposition

Patients suspected to have malrotation require definitive imaging and an immediate surgical evaluation. If the diagnosis is confirmed or equivocal, hospital admission and surgical management are required.

■ NECROTIZING ENTEROCOLITIS

Perspective

NEC is the most common GI emergency in neonates, affecting 2000 to 4000 infants in the United States every year. NEC also is the most common cause of intestinal perforation occurring during the newborn period. Because most affected infants are premature and acquire the condition in the neonatal intensive care unit, NEC usually is not considered a disease of the emergency department (ED). Many of these infants may be discharged relatively early, however, because they are “feeding and growing” and come to treatment in the first month of life. Ten percent of infants with NEC were full-term
babies. Development of NEC is related closely to gestational age. In infants born at 24 to 28 weeks of gestation, NEC develops within 2 to 4 weeks of life; in those born at 29 to 32 weeks of gestation, it is seen within 1 to 3 weeks of life. Among more mature, or full-term, infants, NEC tends to develop in the first week of life. Complications in children who survive NEC may include strictures (seen in 10 to 20% of cases), fistulas, and short gut syndrome.

**Principles of Disease**

The exact pathomechanism in NEC is unclear but seems to be multifactorial. Proposed risk factors include prematurity, aggressive enteral feedings, birth-related hypoxic-ischemic insults, and infectious causes. Prematurity is the most common and universally accepted risk factor; 90% of all affected infants were premature at birth. Rapid advancement of feedings also has been associated with increased rates of NEC. Infec-

**Clinical Features**

Infants with NEC present with feeding intolerance and emesis. Emesis may be either nonbilious or bilious. Occasionally, individual loops of bowel become distended with air and are palpable on abdominal examination. In the more severe stages of the disease, infants may be extremely ill-appearing, with hematemesis, hematochezia, and shock. NEC commonly is placed into one of three clinical stages based on criteria developed by Bell. Stage I represents early or suspected NEC based on feeding intolerance, vomiting, or ileus. Stage II represents definite NEC as proved by abdominal radiographs showing intestinal dilation and pneumatosis intestinalis. Stage III represents advanced disease and is associated with perforation. Infants in this stage are acutely ill, with marked abdominal distention, metabolic acidosis, disseminated intravascular coagulation, and shock.

**Diagnostic Strategies**

Dilated loops of bowel are a common but nonspecific finding in stage I. Another early and more specific radiographic sign is the loss of a normal symmetrical gas pattern and replacement with an asymmetrical pattern of bowel gas, with a variable degree of dilatation. Intramural air (pneumatosis intestinalis) is specific for NEC and is present in stage II (Fig. 170-6). Pneumatosis is present in 75% of patients with NEC. Also may be seen within the biliary tract (portal vein gas) or occasionally in the gastric wall (“pneumatosis gastralis”) (see Fig. 170-6). Portal vein gas is present in 10 to 30% of cases. Ultrasoundography and barium enema, which have been described as adjunctive diagnostic imaging modalities in patients with suspected NEC, are rarely helpful in the ED. No individual laboratory features are diagnostic or specific for NEC.

**Differential Considerations**

Etiologic possibilities vary depending on whether the emesis is bilious and whether the course of vomiting has been sudden in onset, gradually progressive, or chronic (see Table 170-3).

Gastroesophageal reflux classically begins early in life, usually shortly after birth, and remains relatively constant in character. Pyloric stenosis–related vomiting does not begin until 2 to 3 weeks of age and then becomes increasingly severe and projectile. In neonates, bilious vomiting requires careful consideration to rule out the possibility of malrotation with volvulus. As noted previously, with malrotation, a paucity of small bowel air usually is noted on plain films, whereas with NEC, diffusely dilated loops of small bowel typically are seen. In addition, the presence of pneumatosis is diagnostic of NEC but is not a radiographic feature of malrotation.

**Management**

Patients suspected to have NEC should receive nothing by mouth (i.e., be on NPO status), with placement of decompression of either an orogastric or nasogastric tube for decompression of the stomach and small bowel. These patients frequently appear quite ill and may have periods of apnea or significant respiratory distress. The airway should be secured as indicated. Intravenous access should be established and routine laboratory studies performed, to include CBC, electrolyte panel, type and screen, and coagulation studies (prothrombin time/partial thromboplastin time [PT/PTT]). A bedside blood glucose value should be obtained. Cultures of the blood and urine also are indicated. Careful attention should be given to managing fluids and electrolytes because considerable third spacing of fluids may occur in these patients. Repeated fluid boluses at 20 mL/kg of normal saline should be administered until adequate circulation is obtained. These boluses may be augmented with dopamine or epinephrine drips as necessary for patients in refractory shock when euvolemia has been
achieved. Fluids should be continued with 5% dextrose in water and half-normal saline at a minimum of 1.5 to 2 times maintenance. Ill-appearing infants require broad-spectrum, triple-antibiotic coverage with ampicillin, gentamicin, and either clindamycin or metronidazole. Emergent consultation should be obtained from a pediatric surgeon. Patients with evidence of perforation, peritonitis, or gangrenous bowel require surgical intervention. Only one half to three quarters of patients with perforation have free air detectable on radiographs.23

Disposition
Children suspected to have NEC require hospital admission and pediatric surgical consultation.

GASTROESOPHAGEAL REFLUX

Perspective
Gastroesophageal reflux, one of the most common causes of vomiting during infancy, refers to the regurgitation of stomach contents into the esophagus.

Principles of Disease
Gastroesophageal reflux occurs as a result of an incompetent lower esophageal sphincter. Chronic reflux of gastric contents into the esophagus may result in esophagitis, aspiration, and, if severe, failure to thrive.

Clinical Features
Clinical manifestations occur along a wide spectrum of disease, ranging from occasional episodes of spitting up to severe, persistent vomiting and failure to thrive. Gastroesophageal reflux generally responds to conservative measures and resolves with age. The disorder may be associated with stereotypical opisthotonic movements, collectively referred to as Sandifer’s syndrome. Affected children exhibit extension and stiffening of the arms and legs and extension of the neck, often accompanied by a shrill or guttural cry. It may be associated with a brief period of apnea and pallor as formula is refluxed into the esophagus. Sandifer’s syndrome most commonly occurs shortly after feeding and usually is not associated with cyanosis.

Diagnostic Strategies
In the ED, the diagnosis of gastroesophageal reflux typically is made on the basis of a careful history and physical examination; however, for ill patients in whom the diagnosis is uncertain, other diagnostic studies are available with gastroenterology consultation, such as esophageal pH probes to check for reflux of acid, barium swallow, and direct visualization by endoscopy.

Differential Considerations
Children with gastroesophageal reflux exhibit nonbilious emesis that begins shortly after birth and is relatively constant over time. Typically, no sudden starting or ending point, as would be suggested by an acute obstruction, can be identified. Vomiting usually is neither gradually progressive nor projectile, as seen with pyloric stenosis. Most children with gastroesophageal reflux of milder severity continue to gain weight.

Management
Most infants respond to conservative measures, such as smaller feedings, frequent “burpings,” thickening of formula with cereal, and maintaining a semi-upright position for 45 minutes to 1 hour after feeding. Pharmacologic regimens are reserved for more severe cases. Weight loss is an important historical feature and necessitates pediatric gastroenterology referral for evaluation. Children exhibiting failure to thrive or esophagitis often are placed on medical management with ranitidine and metoclopramide. Ranitidine, a histamine blocker, reduces gastric acid secretion. Metoclopramide increases lower esophageal tone, reduces pyloric sphincter tone, and increases gastric motility. Patients not responding to medical management occasionally require surgical intervention with a Nissen fundoplication, which involves wrapping a portion of the stomach around the esophagus to prevent the reflux.

Disposition
Most children can be discharged home safely with conservative measures. Children who exhibit failure to thrive should be referred to a pediatrician or pediatric gastroenterologist for consideration of pharmacologic management. Children with dehydration and children in whom other diagnoses have yet to be excluded may benefit from hospital admission and further evaluation.

INTUSSUSCEPTION

Perspective
Intussusception is the most common cause of intestinal obstruction in children younger than 2 years of age and occurs most commonly in infants 5 to 12 months of age.23 An estimated incidence of 1 per 2000 children younger than 15 years of age, with a male predominance, has been reported.23 Siblings of affected children have a relative risk 15 to 20 times higher than in the general population. The mortality rate for untreated intussusception is high.

Principles of Disease
The exact etiology of intussusception is unclear, but the most prevalent theory relates to a lead point that causes telescoping of one segment of intestine into another.25 As the process continues and intensifies, edema develops and obstructs venous return, resulting in ischemia of the bowel wall. As ischemia of the bowel wall continues, peritoneal irritation ensues, and perforation may occur.

In younger children, lead points are most often the result of enlarged Peyer’s patches secondary to a recent viral infection. In children older than 5 years, an underlying lesion is found in more than 75% of cases; lesions include Henoch-Schönlein purpura (HSP) vasculitis, Meckel’s diverticulum, lymphoma, polyps, postsurgical scars, celiac disease, and cystic fibrosis.24-28

Intussusception may occur at any point along the GI tract. Ileocolic intussusception are most common. Ileoileal intussusception may occur in children with HSP.

Clinical Features
The classic triad of clinical findings in intussusception consists of abdominal pain, vomiting, and bloody stools. All three features are present in less than one third of patients, however. Three quarters of patients with intussusception have two of these findings, and 13% have either none or only one.26 In a
typical presentation, the child experiences cyclic episodes of severe abdominal pain. The pain typically lasts 10 to 15 minutes and has a periodicity of 15 to 30 minutes. During the painful episodes, the child is inconsolable, often described as drawing the legs up to the abdomen and screaming in pain. The clinical presentation occasionally does not include more typical evidence of pain; instead, the child presents with profound lethargy. Vomiting and diarrhea may be associated features. Blood may be present in either the stool or the emesis. Diarrhea containing mucus and blood constitutes the classic “currant jelly” stool most often associated with intussusception, although in actuality this finding is relatively infrequent. Children often have had a recent viral illness. Palpation of the abdomen may reveal a sausage-like mass in the right upper quadrant representing the actual intussusceptum and an empty space in the right lower quadrant representing the movement of the cecum out of its normal position. This combination of findings is called Dance’s sign and is considered pathognomonic for intussusception. Its occurrence is relatively uncommon, however. Intussusception usually is not associated with a high fever; however, low-grade fevers may occur.

**Diagnostic Strategies**

Initial screening films should be obtained, with a minimum of two views of the abdomen. Attention should be focused on visualizing the entire colon and in particular the cecum. Films also should be examined for evidence of a soft tissue mass or mass effect, obstruction, a target sign (representing air in the intussusceptum as it telescopes into adjacent bowel), a meniscus sign (representing air compressed like a meniscus from invaginating bowel), and free air (Fig. 170-7). Normal findings on radiographs of the abdomen revealing complete visualization of the entire colon, including the cecum, make intussusception unlikely; however, indeterminate or nonspecific findings on films in which the entire colon cannot be visualized do not rule out intussusception and require additional imaging. Ultrasonography is the least invasive and most commonly used modality for visualizing intussusception. Ileocolic intussusceptions are most common and are easily detected by ultrasonography, even in inexperienced hands. The goal of the ultrasound exam is to visualize the ileocecal junction, which should be in the right lower quadrant but may be translocated into the right middle to upper quadrant. On the ultrasound scan, the intussusception mass appears as a multilayered or wrapped complex mass, and on longitudinal scan as a tube within a tube as the ileum projects up into the cecum (Fig. 170-8A and B). Because of the readily identifiable anatomic location, and the absence of ionizing radiation, this is usually the diagnostic imaging modality of choice. Contrast enemas may be both diagnostic and therapeutic and in intussusception will reveal a sharp cutoff at the point where the intussusceptum meets the contrast material (Fig. 170-9). Air contrast enemas are equally efficacious, have success rates averaging greater than 60%, and are preferred by some physicians over barium contrast studies. Either type of enema requires readily available backup by a pediatric surgeon in the event of failure of the bowel to reduce or perforation. Before any radiologic studies are performed, intravenous access should be established and the patient should receive at least one...
20-mL/kg bolus of normal saline along with appropriate parenteral pain relief.

**Differential Considerations**

Differential considerations for abdominal pain in children by age are listed in Table 170-4. Slow, progressive onset of pain is more likely to be associated with appendicitis, constipation, or pancreatitis. Children with peritoneal irritation invariably lie still, often on the side with the knees bent, and refrain from all extraneous movement. Sudden onset of severe pain is associated most often with acute obstruction or vascular occlusion, as seen with intussusception, volvulus, or torsion of the testicle or ovary. Children with intussusception have severe colicky pain and often rock back and forth, frequently moaning or crying. Children with ischemic pain exhibit symptoms out of proportion to the findings on examination. They may appear diaphoretic, clammy, or pale and complain of excruciating abdominal pain, although exhibiting only mild tenderness to palpation and no localizing findings.

**Management**

Patients require intravenous access and screening CBC and electrolytes. Intravenous fluids are given in boluses of 20 mL/kg of normal saline until adequate vascular volume is achieved. Children should be maintained on NPO status. Nasogastric tube decompression may be necessary if there is evidence of significant gaseous distention. Prompt surgical consultation is required. Ill-appearing or febrile children require broad-spectrum, triple-antibiotic coverage with ampicillin, gentamicin, and either clindamycin or metronidazole. Diagnostic and therapeutic interventions depend on location and resources available. Patients may undergo an initial ultrasound exam, or if history and plain film findings suggest intussusception, the patient may go straight to either air or hydrostatic barium enema. Surgical intervention is required if the reduction is unsuccessful or if perforation occurs. The overall success rate for air contrast enema or barium enema approaches 90%. Intussusception may recur in 7 to 10% of radiologic reductions and in 2 to 5% of surgical reductions, usually within 24 hours. Admission for observation usually is recommended for all patients after reduction.

**Disposition**

Children with suspected intussusception require definitive imaging with ultrasonography. Children with documented intussusception require reduction with either enema or surgery. Hospital admission is recommended for all patients after reduction.

HIRSCHSPRUNG’S DISEASE

Perspective

Hirschsprung’s disease accounts for approximately 20% of cases of partial intestinal obstruction in early infancy. Hirschsprung’s disease occurs at a rate of 1 in 5000 live births and is four to five times more common in boys. It usually is sporadic in occurrence but may be associated with Down syndrome or a variety of other anomalies of the GI, genitourinary, or central nervous system.34

Principles of Disease

Hirschsprung’s disease represents congenital aganglionosis of the colon and is characterized by an absence of ganglion cells in the myenteric plexus of the distal colon.34 The anus is invariably involved, with aganglionic bowel usually extending proximally 4 to 25 cm. Absence of colonic ganglion cells interferes with that segment’s ability to relax, creating a functional obstruction. Stool accumulates proximal to the level of obstruction and produces dilation of the colon, the so-called megacolon.

Clinical Features

Neonates with Hirschsprung’s disease often present in the nursery with failure to pass meconium. Infants brought to the ED may have a history of constipation and obstipation. Vomiting, irritability, and abdominal distention may be features. Symptoms and signs may be subtle and include a history of chronic constipation and poor weight gain or failure to thrive. Hirschsprung’s disease usually is diagnosed in infancy; however, a spectrum of disease is recognized, and presentation may be later in life. Children who are ill-appearing with fever should be evaluated for enterocolitis and toxic megacolon. Enterocolitis is characterized by abdominal distention, bloody stools, fever, and an elevated white blood cell count. Patients with enterocolitis require broad-spectrum, triple-antibiotic coverage with ampicillin, gentamicin, and either clindamycin or metronidazole. Urgent consultation should be made with a pediatric surgeon. Definitive therapy is surgical, with resection of the aganglionic segments. Acquired megacolon is managed by decompressing the colon and addressing the underlying problems.

Diagnostic Strategies

Plain films of the abdomen may reveal evidence of fecal impaction with proximal obstruction, air-fluid levels, and dilated colon. A barium enema revealing a narrowed aganglionic segment with proximal dilation is highly suggestive of Hirschsprung’s disease.34,35 The diagnosis is confirmed by biopsy or manometry.

Differential Considerations

Constipation is one of the most common causes of abdominal pain and vomiting in children.35,36 Children in the process of “potty training” occasionally become pathologic in their ability to delay defecation. Pathologic causes of constipation are uncommon. In addition to Hirschsprung’s disease, considerations include cystic fibrosis, infantile botulism, and hypothyroidism. An acquired variant of the disease also may occur in which other factors produce similar dilated colonic findings, resulting in acquired megacolon. Risk factors include anal fissures, fecal impaction, toilet training issues, and neuromuscular dysfunction secondary to neurologic disease, drugs, or metabolic causes.

The exact definition of constipation is elusive because it varies with age and diet. Infants during the first few months of life may have stool frequencies that range from one per feeding to one every other day, with breast-fed infants having more frequent stools than formula-fed infants. Frequency continues to decrease with age such that during the first year of life, infants may average two to three stools per day, and from 1 to 5 years of age, one or two per day. Defecation occurs as a combination of physiologic, behavioral, and psychological factors. Relaxation of the external sphincter required for defecation is under voluntary control, whereas relaxation of the internal sphincter is involuntary. Children with a history of unpleasant or painful experiences associated with defecation may contract the external sphincter voluntarily in an effort to delay defecation for as long as possible. Accumulation of stool over time causes the rectum to dilate and decrease its propulsive activity, resulting in an increasing capacity for stool and chronic constipation. Acute episodes may be the result of dietary changes, travel, lack of normal exercise, or stress.

Management

Initial management is focused on ensuring adequate fluid and electrolyte status. Abdominal films should be obtained. With evidence of acute obstruction, seen as marked dilation, decompression may be necessary. Decompression usually can be accomplished easily with a rectal tube. Children who are ill-appearing with fever should be evaluated for enterocolitis and toxic megacolon. Enterocolitis is characterized by abdominal distention, bloody stools, fever, and an elevated white blood cell count. Patients with enterocolitis require broad-spectrum, triple-antibiotic coverage with ampicillin, gentamicin, and either clindamycin or metronidazole. Urgent consultation should be made with a pediatric surgeon. Definitive therapy is surgical, with resection of the aganglionic segments. Acquired megacolon is managed by decompressing the colon and addressing the underlying problems.

Management of constipation requires three considerations: cleanout, maintenance, and behavior modification. Acute constipation is easier to manage because fewer functional problems are involved. The acute management of constipation usually is relatively easy and requires primarily the cleaning out of stool. Most experts recommend an approach that includes stool softeners or laxatives from above and suppositories or enemas from below. In milder cases, only the administration of enemas is necessary to soften feces and stimulate defecation. Tap water, Castile soap, and oil enemas all are generally equally efficacious. Maintenance includes keeping the stool soft for as long as necessary using stool softeners or laxatives. Dietary modifications include increasing fiber and water in the diet and avoiding foods that may be constipating. Management of chronic constipation is more difficult and usually requires a multidisciplinary approach with attention to behavior modification. Children with an underlying pathologic process, such as cystic fibrosis, may benefit from more intense measures, such as administration of large volumes of polyethylene glycol (GoLYTELY).

Disposition

Unless children are ill-appearing, most can be managed safely on an outpatient basis.

MECKEL’S DIVERTICULUM

Perspective

Meckel’s diverticulum is the most common congenital malformation of the small intestine and follows the rule of 2s: The diverticulum is 2 cm wide and 2 cm long and usually located within 2 feet of the ileocecal valve. Moreover, the condition occurs in 2% of the population, and only 2% of affected patients...
ever become symptomatic.\textsuperscript{37} One half of all patients with the condition become symptomatic by the age of 2 years, and most present by age 20.\textsuperscript{37}

**Principles of Disease**

Diverticula are remnants of the omphalomesenteric duct and contain bowel wall, with 60% containing heterotopic tissue.\textsuperscript{38} This tissue most commonly involves gastric mucosa, but other types include pancreatic, duodenal, and endometrial tissue.\textsuperscript{36-38} Bleeding occurs when acid secretion from ectopic gastric mucosa causes ulceration and erosion.

**Clinical Features**

Patients are classically boys younger than 5 years of age who present with massive, painless rectal bleeding of acute onset; however, it can occur at any age. Some children may have some complaints of abdominal cramping. The blood often is described as brick red in color. Complications may include intussusception, obstruction, perforation, and peritonitis.

**Diagnostic Strategies**

A technetium scan, also known as a Meckel’s scan, is the diagnostic modality of choice and has an accuracy of 90% when ectopic gastric mucosa is present.\textsuperscript{39} Administering pentagastrin, cimetidine, or glucagon may increase the sensitivity of the test.\textsuperscript{40} CT scan of the abdomen may be obtained to look for signs of obstruction or if the diagnosis is unclear. Definitive diagnosis is confirmed by laparoscopy or laparotomy.

**Differential Considerations**

GI bleeding is uncommon in childhood. The first step in evaluating a child with suspected GI bleeding is to determine whether the substance is actually blood. Children commonly eat or drink substances containing dyes that lead to factitious changes in the stool’s color. A simple Hemoccult test of the stool or Gastroccult test of the emesis can document the presence of hemoglobin. False-positive results may occur with red meat and iodine. Patients consuming products with bismuth (Pepto-Bismol), iron, and spinach may have black stools falsely appearing as melanotic; they test Hemoccult-negative.

After it has been determined that the substance is blood, the second step is to determine its origin. The location of bleeding often is difficult to determine but may be theorized based on the appearance of the blood. Hematemesis implies bleeding proximal to the ligament of Treitz. Blood exposed to gastric acids for any period of time develops the classic coffee-ground appearance. Bright red upper GI bleeding implies either more proximal bleeding, such as from varices or esophagitis, or brisk gastric or duodenal bleeding. Bleeding that originates beyond the ligament of Treitz but proximal to the ileocecal valve results in melena. Hematochezia, with a visibly red to maroon appearance of the blood, implies bleeding from the descending colon. Distal lesions, such as fissures or hemorrhoids, can result in bright red blood. Barium contrast studies of the upper and lower GI tract sometimes are helpful; however, nuclear medicine scans (Meckel’s scan) are the procedure of choice in detecting Meckel’s diverticulum. Endoscopic examination has the highest rate of determining the location of bleeding; however, the diagnosis often is confirmed first on Meckel’s scan.

In neonates, the most common etiologic category of gastrointestinal bleeding is idiopathic. Careful examination of the rectum should be performed, because the most identifiable cause for bleeding is a fissure or excoriation of the perirectal area. In young neonates, an Apt test may be performed to determine if the blood is maternal or fetal: One percent sodium hydroxide is added to the bloody stool. Fetal hemoglobin resists oxidation and remains pinkish red, whereas maternal hemoglobin changes to a dark brown color.

Another common cause for GI bleeding in infancy is milk protein allergy. Affected children typically are younger than 6 months of age with a history of sudden-onset mucoid, blood-streaked stools. Children otherwise appear well. Although the causative allergy most commonly is to milk protein, GI bleeding may occur with consumption of any protein and has been described in relation to soybean-based products. Children with persistent perianal excoriations and fissures refractory to standard emollients may be infected with group A streptococci and may benefit from treatment with an oral penicillin. Table 170-5 lists the differential considerations for GI bleeding in children by age.

**Management**

Management of GI bleeding begins with assessing and ensuring adequate circulatory status. Screening laboratory studies should include a CBC, coagulation studies (PT/PTT), and a type and screen. Two radiographic views of the abdomen should be obtained in patients in whom obstruction or perforation is suspected. A technetium scan is the imaging modality of choice to evaluate for Meckel’s diverticulum. Consultation with a pediatric surgeon should be obtained.

**Disposition**

Children with suspected Meckel’s diverticulum should undergo a Meckel’s scan. Children with minor bleeding and normal findings on screening laboratory studies may be followed closely on an outpatient basis. Children with more active bleeding should be hospitalized for care by either a pediatric surgeon or a pediatric gastroenterologist.

■ HENOCH-SCHÖNLEIN PURPURA

**Perspective**

HSP, also known as anaphylactoid purpura, is a systemic vasculitis commonly associated with abdominal pain and rash. It is most common in children 4 to 11 years of age but also may occur in adults. HSP occurs most commonly in the spring after a viral upper respiratory infection. It also has been associated with insect stings and certain drugs.\textsuperscript{41}

**Principles of Disease**

HSP is a hypersensitivity vasculitis with immune complex deposition with immunoglobulin A, mainly affecting the arterioles and capillaries. Although it is most well known for its characteristic petechial-to-purpuric rash, HSP is a systemic vasculitis and may affect any blood vessel. Less common manifestations are seen in cases in which the disease is more severe or widespread.

**Clinical Features**

Symptoms include abdominal pain, nausea, vomiting, and diarrhea. Patients most often are diagnosed clinically on the basis of the presence of a classic rash, abdominal pain, microscopic hematuria, and arthralgias. The classic rash is palpable purpura located on the buttocks and lower extremities (Fig.

GI, gastrointestinal.

### Diagnostic Strategies

Patients most often are diagnosed clinically on the basis of the presence of a classic rash, abdominal pain, microscopic hematuria, and mild arthralgias. Screening studies should include a CBC with differential and platelet counts, urinalysis, blood culture, and sedimentation rate determination. Children with worrisome abdominal pain require CT to rule out ileoileal intussusception.

### Differential Considerations

The most important entity in the differential diagnosis for this type of rash is meningococcemia, in which the patient has a fever and looks very ill. It is essential to rule out meningococcemia, because the condition is life-threatening and requires an entirely different approach to management involving hospitalization, fluid resuscitation, and intravenous antibiotics. The classic triad of palpable purpura, abdominal pain, and hematuria in an otherwise well-appearing child virtually ensures the diagnosis. Erythema nodosum occasionally is confused with the rash of HSP; however, in erythema nodosum the rash is described most often as subcutaneous purplish red nodules with the appearance of a bruise located on the extensor surfaces of the distal extremities. Erythema nodosum usually involves only the shins but in more severe cases also may involve the forearms, hands, and feet.

### Management

Most children with HSP can be managed with close follow-up and require no treatment other than symptomatic support. Severe or intermittent abdominal pain in children with HSP is suggestive of intussusception; imaging to investigate this possibility should be done with a CT scan, because ileoileal...
Intussusception may occur and is not detected easily by ultrasonography. Management with steroids is controversial. Corticosteroids, at a dose of 1 mg/kg/day (maximum 60 mg), are reserved for patients with illness on the more severe end of the spectrum, with abdominal pain, hematuria, or arthralgias.

**Disposition**

Indications for hospital admission include uncertain diagnosis to exclude the possibility of meningococcemia, severe abdominal pain, and vomiting. Most patients can be managed safely with close outpatient follow-up.

### INFLAMMATORY BOWEL DISEASE

#### Perspective

The two major entities included within the category of inflammatory bowel disease (IBD) are Crohn’s disease and ulcerative colitis. Approximately 20% of patients present before the age of 20 years. Most patients do not experience symptoms until adolescence, although childhood presentations have been described. IBD is rare in children younger than 1 year of age.

#### Principles of Disease

**Ulcerative colitis** is an inflammatory disease primarily involving the mucosa and submucosa of the rectum and distal colon. **Crohn’s disease** is a transmural inflammatory disease that may involve any portion of the intestinal tract. The most common area of involvement in cases with single-segment disease is distal ileum; however, multiple segments in different areas may be involved. Chronic inflammation may result in the formation of abscess, fistula, or stricture.

#### Clinical Features

Although patients experiencing complications frequently present to the ED, the diagnosis is rarely made in this setting. More commonly, children with known disease present in the midst of a flare, usually with bloody diarrhea and abdominal pain. Extraintestinal manifestations also occur and include fever, anemia, oral ulcerations, erythema nodosum, pyoderma gangrenosum, uveitis, liver dysfunction, and failure to thrive. Some of these manifestations may occur even before the child has experienced any GI symptoms. The most feared complication is toxic megacolon, which classically manifests with abdominal pain, fever, and bloody diarrhea and is associated most often with ulcerative colitis.

#### Diagnostic Strategies

Flares of IBD are diagnosed by the presence of increased frequency of diarrheal or bloody stools and abdominal pain. Patients who are ill-appearing require plain films of the abdomen to rule out toxic megacolon. Patients with toxic megacolon usually have a fever, appear volume-depleted, and demonstrate significant abdominal tenderness to palpation. X-ray films reveal dilatation of the transverse colon to more than 6 to 7 cm in diameter. Free air also should be looked for, because perforation may occur. Screening laboratory studies should include a CBC with differential and platelet counts, type and screen, coagulation studies (PT/PTT), and electrolyte panel.

### Differential Considerations

There are a wide number of differential considerations for abdominal pain and GI bleeding (see Tables 170-4 and 170-5). Gastroenteritis is the most common consideration in this clinical scenario. Children experiencing their first episode of IBD are much more likely to be misdiagnosed with an acute gastrenteritis. Children outside the usual age at presentation also are more likely to be misdiagnosed with gastroenteritis. Children with recurrent symptoms or a family history of IBD should be referred to a pediatric gastroenterologist for further evaluation.

#### Management

Steroids constitute the mainstay of treatment for acute exacerbations. Prednisone at a dose of 1 mg/kg/day (maximum 60 mg/day) usually is recommended and should be provided in consultation with a pediatric GI specialist. Other agents commonly used include sulfasalazine, azathioprine, and a host of other immunosuppressive agents. Management in the ED begins with attention to volume status and resuscitation with boluses of 20 mL/kg of normal saline until the volume status is adequate. Patients with suspected toxic megacolon require intravenous broad-spectrum, triple-antibiotic therapy (with ampicillin, gentamicin, and metronidazole) and immediate surgical consultation.

#### Disposition

Indications for admission include children who are dehydrated, febrile, or ill-appearing. Children with ongoing diarrhea productive of bloody stools usually benefit from intravenous fluids until the flare has been controlled. Children with evidence of toxic megacolon require surgical consultation and admission.

### GASTROINTESTINAL FOREIGN BODIES

#### Perspective

Most GI foreign bodies occur in toddlers, who experience life by first putting it in their mouths. Children younger than 3 years of age are particularly at risk because of the combination of inappropriate mouthing of objects and a general lack of coordination in swallowing. Although food is the most common esophageal foreign body in adults, coins are most common in children. Children with mental retardation swallow a variety of objects. Adolescents occasionally swallow objects in an attempt at suicide. Rectal foreign bodies are uncommon in the pediatric age group.

#### Principles of Disease

Most swallowed foreign bodies pass without difficulty. Foreign bodies may become lodged in any of three areas of normal physiologic narrowing: upper esophageal sphincter (cricopharyngeus muscle)/thoracic inlet (C6-T1), the aortic arch/tracheal bifurcation (T4-6), and the lower esophageal sphincter/diaphragmatic hiatus (T10-11). In general, 80 to 90% of objects that have made it into the stomach are passed without difficulty.

#### Clinical Features

The classic clinical presentation is that of a child who is seen from across the room putting coins in his or her mouth. Children frequently gag and sputter as they attempt to swallow the
object. Aspirated objects generally produce persistent coughing, wheezing, or increased work of breathing. Objects that have been swallowed may result in the child’s remaining asymptomatic or may produce symptoms ranging from persistent gagging to drooling and continuous dry heaves. Larger foreign bodies may compress the airway and cause significant respiratory distress. Rapidly progressive symptoms of dysphagia, pain, respiratory distress, or fever raise the possibility of a perforation. Perforation is uncommon, even with sharp objects such as straight pins. The ileocecal valve is the most common site for perforation, which occurs in less than 1% of patients. Button batteries warrant special mention. Button batteries in the esophagus should be removed in as rapid a manner as possible because erosions and mediastinitis ultimately may occur. Button batteries in the stomach usually pass without difficulty and do not require removal unless they fail to pass the pylorus within 24 to 48 hours of ingestion. Occasionally, objects pass into the stomach that are too large to pass through the pylorus; this is uncommon and is heralded by persistent vomiting. Long-present unrecognized foreign bodies may result in erosion, perforation, infection, stricture, or fistula formation.

**Diagnostic Strategies**

Plain radiography is the most common method of visualizing location and is used to verify positioning past the lower esophageal sphincter into the stomach. Patients who are asymptomatic after foreign body ingestion require imaging to determine location. Occasionally, patients who are asymptomatic also have objects remaining in the esophagus. Radiographs should include anteroposterior and lateral views of the chest and neck (Fig. 170-11). The lateral view helps to delineate soft tissues in the hypopharynx and to evaluate for swelling, particularly if the foreign body is either unknown or of a nonradiopaque material. Often a single view of the neck, chest, and upper abdomen can be obtained easily in the pediatric patient. Unless the patient becomes symptomatic, repeat films are otherwise never necessary. Asking parents to sieve the stool typically is unproductive, and even sharp objects such as pins or razor blades usually pass through the GI tract without incident. Patients presenting with a history of button battery ingestion represent the exception in that they require repeat films to document passage beyond the pylorus. Rather than using standard radiography, some institutions have noted success with intradepartment fluoroscopy or hand-held metal detectors. Contrast studies may be helpful to delineate nonradiopaque foreign bodies or to evaluate for perforations.

**Differential Considerations**

Not all foreign bodies are radiopaque and visible with standard radiography. Patients who remain symptomatic require further contrast-enhanced imaging or direct visualization.

**Management**

If the object has made it into the stomach, usually it will pass without incident, and no further treatment is necessary. If the foreign body is in the esophagus, most experts recommend removal within 24 hours to decrease the risk of aspiration and esophageal erosion. The preferred method by which to remove esophageal foreign bodies is controversial and varies by institution. Options include fluoroscopic Foley catheter removal, bougienage advancement into the stomach, endoscopic removal in the ED, and removal by rigid bronchoscopy under general anesthesia in the operating room. Foley catheter removal and bougienage do not require sedation in cooperative patients, but young children invariably require sedation in the operating room. With the latter two methods, the technique involves actually holding onto the foreign body, which—at least theoretically—decreases the chance of inadvertent aspiration. They also have the additional benefit of directly visualizing the integrity of the mucosa and evaluating for perforation. Gastric foreign bodies generally do not require removal. Indications for surgical removal of gastric foreign bodies include objects that are greater than 2 cm in width, objects that are greater than 5 cm in length, and objects that are sharp.

**Disposition**

Esophageal foreign bodies require removal as described previously. After foreign bodies have made it into the stomach, most pass without difficulty, and no further follow-up is necessary. Button batteries constitute the exception and necessitate follow-up films to document passage beyond the pylorus.

---

**PANCREATITIS**

**Perspective**

Pancreatitis is uncommon in childhood, especially in children younger than age 10. Pancreatitis has an incidence of approximately 1 case in 50,000 in children and carries a mortality rate
of 14%. In adults, pancreatitis is associated most commonly with alcohol and biliary tract disease. In children, a fairly equal association of approximately 10 to 20% each has been documented for trauma, infection, structural damage, systemic disease, and drugs or toxins. Mumps is the most common viral cause of pancreatitis and accounts for 10 to 15% of all cases. Idiopathic causes account for 30% of cases.

**Principles of Disease**

Whether the result of trauma, obstruction, or inflammation, a series of events occurs, resulting in inflammation, edema, and autodigestion of pancreatic tissue by pancreatic enzymes. In severe cases, the inflammatory process may progress to necrosis and hemorrhage, resulting in necrotizing or hemorrhagic pancreatitis. Further complications include the formation of abscesses, pseudocysts, and fistulae.

**Clinical Features**

Patients classically present with complaints of severe epigastric pain that radiates to the back. Pain is gradually progressive and constant and often is associated with nausea and vomiting. Pain classically is described as being worse with eating. Significant abdominal tenderness usually can be elicited in the epigastric area, accompanied by voluntary guarding and hypoactive bowel sounds. The abdomen may be slightly distended.

**Diagnostic Strategies**

Screening laboratory studies reveal elevations in serum amylase or lipase. Plain films of the abdomen may be indicated to investigate the possibility of free air or obstruction. An ileus pattern is common, often with a sentinel loop of dilated small bowel noted in the left upper quadrant. An ultrasound or CT scan may be helpful to evaluate anatomy for congenital malformations or biliary tract disease and to evaluate for pseudocyst or abscess formation. In patients with pseudocysts, hemorrhagic pancreatitis may develop that may become life-threatening. For patients with respiratory distress, a chest film can be helpful to evaluate for a coexistent pleural effusion caused by the pancreatitis.

**Differential Considerations**

Slow, progressive onset of pain is more likely to be associated with appendicitis, constipation, or pancreatitis. Children with peritoneal irritation invariably lie still, often on the side with knees bent, and refrain from all extraneous movement. Sudden onset of severe pain is associated most often with acute obstruction or vascular occlusion as seen with intussusception, volvulus, or torsion. Differential considerations for abdominal pain in children by age are listed in Table 170-4; differential considerations for the causes of pancreatitis are listed in Table 170-6.

**Management**

Management begins with attention to volume status and correction of electrolyte abnormalities if present. A bedside finger-stick blood glucose value should be obtained. Adequate pain relief with parenteral narcotics should be provided. The patient should be maintained on NPO status and given adequate fluids. Intravenous fluids are given in boluses of 20 mL/kg of normal saline until adequate vascular volume is achieved and then are followed by 5% dextrose in water and half-normal saline at 1.5 times maintenance. Antiemetics are indicated to help control nausea and vomiting. A nasogastric tube usually is not necessary or helpful, unless an ileus or persistent vomiting is present. Steroids and antibiotics are not indicated.

**Disposition**

Most children with pancreatitis require hospitalization, unless they have known or recurrent disease for which an outpatient regimen providing adequate analgesia and hydration is available.

**APPENDICITIS**

### Perspective

Appendicitis is the most common surgical condition involving the abdomen, and the most common nontraumatic surgical emergency in children. Approximately 200,000 appendectomies are performed every year, and appendicitis develops in approximately 1 of every 15 people in the general population sometime during their lifetime. The peak age of incidence of appendicitis is between 9 and 12 years, and it is uncommon in children younger than 5 years of age.

Acute appendicitis has an overall mortality rate of less than 1%. For unruptured appendicitis, the mortality rate is 0.1%; the mortality rate increases to approximately 3% for ruptured appendicitis. In children, the rate of appendiceal perforation before surgery varies, ranging from 17 to 40%, and is inversely
related to age, with higher rates of perforation occurring in younger age groups. In children younger than 2 years of age, perforation will have occurred in 90% by the time of surgery.

Principles of Disease

The appendix is a blind pouch that may become obstructed. After it is obstructed, a vicious circle is established, with increasing edema, vasocongestion, inflammation, ischemia, infarction, necrosis, and perforation. In adults, a thicker appendiceal wall protects against perforation, and a well-developed omentum aids in walling off the infection to prevent its diffuse spread. Children have neither, so rupture tends to occur earlier and diffuse peritonitis develops more readily.

Clinical Features

Patients classically present with a constellation of symptoms that includes abdominal pain, nausea, vomiting, fever, and anorexia. All of these symptoms are gradually progressive over 4 to 24 hours. Abdominal pain usually is described as vague, crampy, and periumbilical on origination, which then becomes more severe, constant, and localized to the right lower quadrant. Fever usually develops later, sometimes not until after the patient already has presented to the ED. Nausea and vomiting are progressive and most often are associated with anorexia. Patients occasionally may have a multiphasic course to their illness, which begins with the classic abdominal pain, with progression of symptoms until they suddenly resolve, followed several days later by development of fever, chills, and abdominal pain. This course represents acute appendicitis with spontaneous rupture and formation of an abscess.

Physical examination may reveal several classic findings. In patients with inflammation surrounding the appendix, peritoneal findings that localize to the right lower quadrant are typical. Pain occurs with movement, so the patient prefers to lie still. Patients are unable to jump up and down and complain that even rocking the bed or tapping their heels causes pain. The abdomen usually is quiet, with an absence of bowel sounds. Rebound tenderness can be elicited in the right lower quadrant. Rovsing’s sign also may be present and consists of severe pain in the right lower quadrant occurring when the examiner presses in the left lower quadrant and rapidly releases the examining hand. Other findings associated with appendicitis include the psoas and obturator signs. The psoas sign is pain elicited by having the patient, in lateral decubitus position, hyperextend the right thigh at the hip, thereby stretching the psoas muscle, which overlies the inflamed appendix. The obturator sign similarly is pain elicited by having the patient internally rotate the flexed right thigh against resistance.

Diagnostic Strategies

Appendicitis may be diagnosed on the basis of history and physical findings alone. Patients with the appropriate constellation of findings consistent with appendicitis may not require any testing and can proceed directly to the operating room for either laparoscopic or open exploration. Patients in whom the diagnosis is suspected usually require some diagnostic workup. Screening studies should include a CBC with differential, urinalysis, and pregnancy test. An estimated 96% of patients with appendicitis have either an elevated white blood cell count greater than 10,000/µL or a left-shifted differential with more than 75% neutrophils. Although an elevated white blood cell count supports the diagnosis, it is not specific for appendicitis. The appendix is in close proximity to the ureters, so appendicitis may induce some degree of sterile pyuria. Inflammatory changes related to appendicitis generally result in fewer than 5 to 10 white and red blood cells per high-power field and an absence of bacteria. Findings in excess of these amounts suggest a urinary tract etiology (e.g., infection, stone, mass, trauma). Consideration also may be given to adding a rapid streptococcal test in patients with a red or sore throat.

Diagnostic imaging options include plain films of the abdomen, ultrasonography, and limited CT scan of the appendix. Plain films help to rule out free air or obstruction and occasionally show an appendiceal fecalith, also called an appendicolith (Fig. 170-12). Although the presence of an appendicolith is essentially pathognomonic for acute appendicitis, it is present in only 10% of cases. Ultrasound findings consistent with appendicitis include an enlarged, noncompressible appendix that is painful during scanning (Fig. 170-13A and B). A fecalith may be evident inside an enlarged and inflamed appendix—the so-called target sign. Appendiceal ultrasound studies have a sensitivity, specificity, and overall accuracy of 90 to 95%. Ultrasound imaging is particularly useful for evaluating for abscesses and fluid collections; however, a great deal of operator and reader variability is characteristic (Fig. 170-13C). Ultrasonography does not involve exposure to ionizing radiation. Using an ultrasound exam as an initial screen for appendicitis, in which only patients with negative or equivocal scans were required to undergo CT, resulted in a sensitivity of 96% and a negative predictive value of 98%.

Limited CT of the appendix is the most recent technology to have emerged in terms of imaging. Limited CT scans of the appendix have sensitivity and specificity rates of 95 to 100%. The ready availability of appendiceal CT has been shown to reduce the negative laparotomy rate from 20% to 7%, with the highest accuracy reported using new focused appendiceal CT techniques with rectal contrast. For patients with relatively low probability of appendicitis, CT may offer a cost-effective screening tool, particularly compared with inpatient admission and observation. Imaging the pelvis and the right lower quadrant (with either CT or ultrasonography) not only establishes the diagnosis of appendicitis but also aids in identifying the two most common considerations in the differential diagnosis: IBD and mesenteric adenitis. An important point is that CT scanning involves exposure to a significant amount of ionizing radiation, which places children at increased risk for future malignancies. Beginning in the past decade, the number of CT scans has increased dramatically (nearly 700%).
even more common than appendicitis. Differential considerations for abdominal pain by age are listed in Table 170-4. Other considerations include nonaccidental trauma (abuse), malingering, and Munchausen syndrome. Girls of reproductive age merit consideration of a gynecologic origin and require a pregnancy test and pelvic examination; the possibility of ovarian torsion, particularly if the pain seems to be severe and out of proportion to physical examination findings, should not be overlooked. Boys require an external genital examination to rule out the possibility of testicular torsion. Cryptorchidism in the face of acute abdominal pain should raise suspicion for testicular torsion.

Management

In patients with suspected appendicitis, NPO status should be maintained and an intravenous line established. Most patients have vomiting and anorexia and benefit from at least one fluid bolus of 20 mL/kg of normal saline and then administration of 1.5 to 2 times maintenance fluids with dextrose 5% in water and half-normal saline. Screening studies should be initiated, and appropriate consultation with a surgeon is indicated. Ongoing pain should be addressed adequately. Intravenous narcotics are safe and effective and should not alter the diagnostic accuracy of the physical examination. Patients with high fever, suspected perforation, or unusual delay to surgery require coverage with intravenous broad-spectrum antibiotics, which should be initiated in the ED after consultation with the surgeon. A reasonable regimen for antibiotic therapy consists of ampicillin, gentamicin, and either metronidazole or clindamycin. Nasogastric tubes are reserved for patients with persistent nausea or vomiting related to abdominal distention or ileus.

Disposition

Children with appendicitis as documented by physical examination or diagnostic imaging are hospitalized for appendectomy. Patients with nonspecific symptoms and signs who do not undergo definitive diagnostic study can be hospitalized and observed for a period of 12 to 24 hours or, with adequate family and social support, can be discharged home with careful instructions to return for reexamination.
are seen most commonly in hemolytic anemia, such as from sickle cell disease and spherocytosis. Gallstones occurring in infants usually are associated with abdominal surgery, sepsis, necrotizing enterocolitis, or administration of total parenteral nutrition. In young children, gallstones most commonly develop as a result of their hemolytic disease. Adolescents form gallstones in association with oral contraceptives, pregnancy, obesity, or underlying hemolytic disease. In acute acalculous cholecystitis, the ultrasound scan will reveal evidence of gallbladder inflammation in the absence of calculi. Hydrops of the gallbladder is an acute noninflammatory, noninfectious process that results in a markedly enlarged gallbladder without evidence of calculi.

**Clinical Features**

Similar to adult patients, pediatric patients usually present with right upper quadrant pain that radiates through to the back and may be associated with fever, nausea, and vomiting. Jaundice occurs in one third of patients.

**Diagnostic Strategies**

Biliary tract disease usually is associated with elevations in liver enzymes and bilirubin; however absence of elevations does not exclude the diagnosis. Accordingly, right upper quadrant ultrasound imaging may be prudent in cases in which gallbladder disease is suspected. Elevations in alkaline phosphatase suggest cholestasis. Elevated white blood cell counts are nonspecific but if associated with fever may represent an acute infective process (e.g., ascending cholangitis). Ultrasonography is the imaging modality of choice. It can determine the presence of gallstones, reproduction of pain on scanning (sonographic Murphy’s sign), the amount of dilatation of the gallbladder and bile ducts, gallbladder wall thickness, and the anatomic configuration of the biliary and pancreatic collecting system. When ultrasound findings are equivocal or negative in the face of strong clinical evidence, the gold standard modality for biliary tract imaging is still considered to be cholescintigraphy (DISIDA scanning); rarely, percutaneous cholecystocholangiogram is necessary. Although only 15% of gallstones in adults are calcified and visible on plain radiographs of the abdomen, 50% of stones are visible in children.

**Differential Considerations**

Biliary tract disease is uncommon in children and requires consideration of underlying or coexistent disease. Differential considerations for abdominal pain by age are listed in Table 170-4.

**Management**

Management of biliary tract disease begins with attention to fluid and electrolyte status. Adequate pain control should be provided, usually with a parenteral opioid. Asymptomatic patients with incidental findings of gallstones require no further therapy in the ED and may be referred to a surgeon for outpatient care. Patients who are afebrile usually can be managed safely on an outpatient basis with adequate pain control. Febrile patients require hospital admission and intravenous antibiotics. A reasonable regimen for empirical antibiotic coverage consists of ampicillin and gentamicin, plus either clindamycin or metronidazole.

Several management options have been used in the treatment of children with cholecystitis: medical management with ursodeoxycholic acid to dissolve the stone, expectant management, and surgical management. Laparoscopic cholecystectomy is considered safe and effective in children.

**Disposition**

Indications for hospital admission include pain control, hydration, fever, and need for operation.

---

**KEY CONCEPTS**

- Physiologic jaundice of the newborn and breast milk jaundice are the most common causes of jaundice in the neonatal period.
- Direct hyperbilirubinemia in infants is always pathologic and requires a detailed workup.
- Hypertrophic pyloric stenosis manifests with gradually progressive nonbilious emesis that becomes projectile.
- Hypochloremic, hypokalemic metabolic alkalosis is the classic electrolyte abnormality for children with hypertrophic pyloric stenosis.
- Bilious vomiting in the neonate should immediately raise the suspicion of malrotation and volvulus.
- In infants with bilious emesis, a toxic appearance, a distended abdomen, or an acute obstructed pattern on abdominal radiographs constitutes a true surgical emergency.
- NEC occurs more commonly in premature infants, but 10% of affected infants are full term.
- Gastroesophageal reflux usually responds to conservative measures (positioning, thickening of formula, smaller and more frequent feedings).
- The classic clinical triad in intussusception comprises abdominal pain, vomiting, and heme-positive stools; however, the triad occurs in fewer than one third of patients.
- Children with intussusception may present without pain and with lethargy alone.
- Hirschsprung’s disease is a common cause of constipation in the neonate and usually is manifested by delayed passage of meconium.
- Meckel’s diverticulum classically manifests in children younger than 5 years of age with painless brick-red rectal bleeding.
- More than 90% of gastrointestinal foreign bodies pass without difficulty.
- Causes of pancreatitis in children include viruses, trauma, drugs, and toxins.
- Imaging strategies for children that include ultrasound examination followed by CT scan of the abdomen have been shown to reduce costs and negative laparotomy rates.
- Cholelithiasis is diagnosed with right upper quadrant ultrasound imaging; management strategies include medical and surgical approaches.

Infectious Diarrheal Disease and Dehydration

Lei Chen

ACUTE INFECTIOUS DIARRHEA

Perspective

Diarrhea is defined as increased frequency, volume, and liquidity of stools. Worldwide, infectious diarrhea is one of the most significant contributors to morbidity and mortality and is responsible for 4 million to 5 million deaths per year in children younger than 5 years of age. Regional differences in resources, epidemiology, underlying general health status of the population, and availability of safe food and water affect the actual disease burden. In the United States, acute gastroenteritis historically accounts for 10% of hospital admissions of children younger than 5 years of age, estimated at 220,000 admissions per year; 300 to 400 deaths per year are caused by diarrhea, most occurring in the first year of life. Children are at higher risk than adults for complications of diarrhea such as hypoglycemia, electrolyte abnormalities, and shock. This vulnerability is due to their smaller physical size, low physiologic reserve, and immature immune system.

In emergency departments (EDs) across the nation, intravenous therapy is widely used for treating volume depletion due to infectious diarrhea. Some potential serious complications have emerged as a result of exuberant use of parenteral rehydration. In many situations, diarrhea-related volume depletion can be treated by enteral replacement, either through oral intake or delivered by way of nasogastric and orogastric tubes. Recent vaccine advances have raised the hope that infectious diarrhea and suffer greater clinical consequences. Among these are premature infants and patients who are immunosuppressed or malnourished or who have a chronic disease. Recent hospitalization, treatment with broad-spectrum antibiotics, and travel to developing countries are additional risk factors.

Principles of Disease

Pathophysiology

Normally the gastrointestinal (GI) tract takes in, secretes, and absorbs a large quantity of fluids. Up to 9 L of fluid from diet and endogenous secretions enter the proximal bowel each day in the adult. In children, a proportionately larger volume of fluid per body weight is ingested and secreted to maintain homeostasis (e.g., 125 mL/kg per 24 hours in adults versus 220 mL/kg per 24 hours in newborns). Ninety percent of the fluid is absorbed in the small bowel and the remainder in the large bowel. Water follows osmotic gradients created by transport of electrolytes, sugars, and amino acids into the bloodstream. Both active transport– and passive transport–facilitated mechanisms are in place. Glucose and certain amino acids are absorbed by active carrier-mediated transport and coupled to sodium absorption. This concept of cotransporter is important in understanding the role of combination of dextrose and sodium in enteral rehydration.

Infectious diarrhea occurs when the fine balance is disrupted, either as a result of increased secretion from the GI tract or because of decreased absorption of fluids. Although this distinction is useful conceptually, cases of infectious diarrhea often occur through both mechanisms.

SECRETORY DIARRHEA is the result of the increased intestinal secretion caused by a variety of mechanisms. In the case of cholera, an enterotoxin causes an increase in cyclic adenosine monophosphatase (cAMP) in the endothelial cell, resulting in increased chloride and bicarbonate secretion. Enterotoxin-producing bacteria include Salmonella and Shigella organisms, Vibrio cholerae, E. coli, and Clostridium difficile. Noninfectious causes of secretory diarrhea are rare and include a variety of neurotransmitters such as prostaglandins, histamine, and other GI hormones. Clinically, secretory diarrhea often is characterized by absence of expected reduction in stool volume with

Epidemiology

In developed countries such as the United States, infectious diarrhea is caused by viruses in 60% of cases; bacteria, 20%; parasites, 5%; and parenteral illnesses, 10%, with 5% caused by unknown agents. Rotavirus is the prototypical viral agent. Bacterial pathogens include Salmonella, Escherichia coli, and Campylobacter jejuni. Giardia and Entamoeba histolytica are common protozoal pathogens. Infectious diarrhea in children most often is contracted through the fecal-oral route and through poor food-handling practices. Daycare centers remain a main source of cases, with infection spread by handling diapers, fecal-oral transmission, and sharing toys. Causative agents may be endemic, epidemic with food- and water-borne outbreaks, or sporadic. For most agents, a large inoculum is required to transmit the illness. The exceptions are Campylobacter, Giardia, and Shigella, for which 10 to 100 organisms are sufficient to cause disease. Some groups are at higher risk for acquiring infectious diarrhea and suffer greater clinical consequences. Among these are premature infants and patients who are immunosuppressed or malnourished or who have a chronic disease. Recent hospitalization, treatment with broad-spectrum antibiotics, and travel to developing countries are additional risk factors.
fasting, a stool pH greater than 6, and absence of reducing substances in the stool.

Osmotic diarrhea is caused by the presence of poorly absorbed solutes in the colon as a result of altered bacterial gut flora, damage to the mucosal absorptive surface, or ingestion of substances. These substances alter the normal mechanisms of fluid transport by creating an osmotic gradient across the bowel lumen. This results in movement of water and electrolytes into the luminal fluid. Typical acute viral gastroenteritis, caused by rotavirus or Norwalk-like virus, produces injury to the small bowel epithelium with consequent disruption of microvilli, thereby decreasing absorptive area and preventing normal fluid, electrolyte, and nutrient absorption. The illness is compounded when the colon is unable to cope with the large fluid volume. Diagnostic clues to an osmotic etiology are diarrhea that decreases or stops with fasting, a stool pH less than 5, and presence of reducing substances in the stool.

Dysentery is defined as diarrhea associated with blood and mucus in the stool. The presence of dysentery often implies that the infection has compromised the bowel wall. Acute inflammation, caused by enteroinvasive organisms such as Salmonella, Shigella, and Campylobacter, leads to infiltration of the GI tract by neutrophils, which in turn release a host of enzymes and factors causing both increased secretion and decreased absorption by the intestinal tract. Although blood loss may be clinically appreciable, it usually is less significant than the fluid and electrolyte losses. Systemic infection should be suspected if clinical signs of prostration, chills, and fever are present, or if an elevated count or left shift is seen on a WBC count.

Diarrhea caused by altered motility, increased or decreased transit time (diabetes, scleroderma, neuromuscular disease), reduced surface area (short gut, celiac disease), or inhibited active ion transport is less common in children presenting to the ED.

Several physiologic factors predispose pediatric patients to more severe complications of infectious diarrhea. During growth and development, children undergo significant changes in the distribution and composition of body fluid compartments. Children have larger extracellular fluid compartments compared with adults and can therefore lose proportionately more fluids through the GI tract. Children have limited stores of metabolic substrates such as fat and glycogen. Young children often have limited ability to access fluids. They are therefore more susceptible to large fluctuations in fluid, electrolytes, or nutrients.

Extracellular fluid loss in acute diarrhea may lead to significant intravascular volume depletion, which in turn may lead to primary metabolic acidosis with varying degrees of respiratory compensation. The metabolic acidosis usually results from the loss of HCO₃⁻ in diarrheal fluid but also may be caused by renal tubular acidosis, excessive lactate production from poor tissue perfusion, and therapeutic interventions (e.g., salicylates). One effect of metabolic acidosis is an increase in minute ventilation. The maximum respiratory compensation in metabolic acidosis is a decrease in PaCO₂ to 12 to 15 mm Hg, which may occur within minutes to hours of onset of the abnormality. Nonvolatile acids, especially sulfur and phosphoric acids, must be excreted by the kidneys; several hours to days will be required for this process to occur. On clinical examination, these children are hyperpneic, with deep and labored breathing, even when they are at rest. Patients with metabolic acidosis from diarrhea require restoration of intravascular volume to allow delivery of nutrient substrate and elimination of by-products of cellular metabolism, rather than rapid correction of the acid-base disorder with buffer alone. Restoration of intravascular volume often corrects what appears to be respiratory distress in the severely volume-depleted child.

Etiology

Acute diarrheal illnesses can be caused by viruses, bacteria, or protozoa. In developed countries such as the United States, viral causes predominate. In countries in which access to clean water and food supply is limited, bacterial agents contribute the major portion of the morbidity and mortality associated with infectious diarrhea.

Virus

The virus responsible for most cases of acute viral gastroenteritis and a disproportionate amount of morbidity caused by diarrheal illness in the United States is rotavirus. This virus is endemic and accounts for nearly one third of the cases in children with diarrhea. The incidence peaks in the winter and spring in temperate climates. Rotavirus causes acute illness with vomiting and diarrhea that may or may not be associated with fever. The diarrhea usually is watery in consistency, and the volume may be large enough to result in significant and rapid intravascular volume depletion. Rotavirus also may cause symptoms of an upper respiratory tract infection. Most infections are transmitted person to person, probably through the fecal-oral route. There is also evidence that it may be transmitted through respiratory secretions as airborne droplets. The incubation period is 1 to 3 days. Postinfection excretion may be prolonged, ranging from 4 to 57 days.

Rotavirus selectively destroys the villus tip cells in the small intestine, leading to malabsorption and diarrhea. A proliferative response occurs, producing an abundance of incompletely differentiated cells in the gut mucosa. In the healthy host, repair of the epithelium and differentiation of the immature brush border take approximately 3 to 5 days and occur without specific intervention. In the chronically ill or malnourished child, the infection leads to complications beyond the usual brush border injury. Failure to repair the epithelium leads to the vicious circle of malnutrition and progressive epithelial injury.

Diagnosis is made by demonstration of the presence of antigens in stool specimens by enzyme immunoassay. Modern assays have up to 97% sensitivity and 97% specificity for rotavirus antigens in human stool. The test can be performed on undiluted stool without special preparation. An effective vaccine was available for a short time until it was noted to be associated with increased risk of intussusception, usually occurring 3 to 20 days after the administration. This vaccine was subsequently withdrawn from the U.S. market.

Another live attenuated rotavirus vaccine, RotaTeq, was approved by the U.S. Food and Drug Administration (FDA) in 2006. In phase III trials it provided good protection from severe diarrheal diseases due to rotavirus. The vaccine is now routinely administered to infants at 2 months, 4 months, and 6 months of age. To date, no association with intussusception has been reported. Nevertheless, vigilance for this problem is in order, and the diagnosis should be considered in a young infant presenting with signs or symptoms of intestinal obstruction, bloody diarrhea, or lethargy.

Norwalk-like viruses, now named noroviruses, are common pathogens in outbreaks of gastroenteritis in all age groups. These viruses can be transmitted person to person, as well as through contaminated food and water sources. Common-source outbreaks in long-term care facilities contribute significantly to morbidity and mortality among the residents. In addition, these agents most commonly are associated with out-
breaks of acute gastroenteritis on cruise ships and in schools and hospitals.

Hepatitis A virus (HAV) infections are seen as an acute febrile illness with anorexia, nausea, vomiting, and malaise. HAV invades the hepatocytes, causing immunologically mediated hepatocellular damage. In children, the infection may manifest as an anicteric illness and be misdiagnosed as a non-viral specific viral gastroenteritis. HAV is not seasonal and is spread by a common food or water source with fecal-oral contamination. The incubation period is 2 to 6 weeks, and patients shed virus for 1 to 3 weeks beginning 1 to 2 weeks before symptoms develop. Subsequent lifelong immunity is the norm. Household contacts should be offered immunoglobulin prophylaxis. Two inactivated hepatitis A vaccines are available in the United States.

Bacteria

The common bacterial organisms causing acute diarrhea in the United States are, in order of frequency, Salmonella species, Shigella species, Campylobacter jejuni, and Yersinia enterocolitica. Enterotoxigenic, enteroinvasive, and enterohemorrhagic strains of E. coli also are found in the United States. Other, less common bacterial causes are Clostridium perfringens, Clostridium difficile, Staphylococcus aureus, Vibrio cholerae, and Vibrio parahaemolyticus, each accounting for less than 1% of cases.

Salmonella infections usually are divided into those caused by Salmonella typhi (typhoid fever) and those involving other species. Nontyphoid salmonellae account for more than 98% of the cases in the United States. Clinical syndromes include a carrier state, acute gastroenteritis, bacteremia, and a disseminated abscess syndrome. It is presumed that the salmonellae invade the mucosa and produce a cholera-like enterotoxin and a cytotoxin. Nontyphoid Salmonella gastroenteritis is an illness marked by nausea and fever, although it may manifest as dysentery or a cholera-like illness. Acute gastroenteritis occurs at any age but is most common in the first year of life. Animal reservoirs include poultry and reptiles, often kept as pets by young children. In general, antibiotics are not recommended for uncomplicated cases of acute gastroenteritis, because such therapy is ineffective in shortening the symptoms and can cause a prolonged carrier state. Antibiotic treatment is indicated in infants younger than 3 months of age or those with complications such as failure to improve within 5 to 7 days, bacteremia, or focal infection in the central nervous system (CNS), bone, joint, kidney, or pericardium. Ampicillin and trimethoprim-sulfamethaxazole (TMP-SMZ) usually are effective. Because of changing resistance patterns, susceptibility testing should be performed on all isolates.

Shigella species consist of four antigenic groups of 40 serotypes. Shigella sonnei is the most common cause of dysentery (diarrhea with significant blood, pus, and mucus) in the United States. Shigellosis usually begins as an enterotoxin-like secretory diarrhea with watery stools and fever that may progress to bacillary dysentery with or without systemic manifestations. Clinical illness varies from mild to severe, with some patients exhibiting abdominal cramps and tenderness. Shigellosis rarely infects infants younger than 3 months of age and is most common between 2 and 3 years of age. Symptoms usually are self-limited and resolve within 72 hours. Extraintestinal symptoms and signs are relatively common in children with Shigella infection and may include hallucinations, confusion, or frank seizures. Reactive arthritis can occur weeks after the infection. Rare complications of Shigella infection include bacteremia and hemolytic uremic syndrome (HUS). Antibiotics are reserved for patients with prolonged symptoms, dysentery, or underlying immune compromise. Approximately 50% of isolates are resistant to ampicillin and TMP-SMZ. Therefore, a fluoroquinolone (such as ciprofloxacin or ofloxacin) in adults or azithromycin in children is recommended for more severe illness.

Campylobacter species cause a significant proportion of diarrheal disease occurring worldwide. The organism is found in the GI tracts and feces of wild and domestic fowl, farm animals, and pets. Of the five types, Campylobacter jejuni and Campylobacter coli are the most common. Illness consists of abdominal cramps, diarrhea, chills, fever, and Shigella-like dysentery. The clinical presentation may be similar to that in acute appendicitis or other surgical conditions. Infection of the mucosa with toxin production has been described. A 1- to 7-day incubation period is normal, and the illness usually lasts less than a week. Campylobacter organisms are transmitted by ingestion of contaminated food or water. Diagnosis is made by darkfield microscopy. Although azithromycin (12 mg/kg daily PO for 5 days) may shorten the course of the illness, most children do not need antibiotic therapy.

Y. enterocolitica is a relatively uncommon cause of simple self-limited diarrhea and vomiting in the United States. Diarrhea may be watery, mucoid, or bloody. As many as 6% of older children and adults may present with an appendicitis-like illness with right lower quadrant tenderness, usually as a result of reactive mesenteric adenitis. The principal reservoirs for Y. enterocolitica are swine and cattle, with infections usually resulting from ingestion of undercooked pork or unpasteurized milk. Duration of the gastroenteritis may be prolonged, to 14 days or more. Antibiotics are indicated in cases of septicemia and extraintestinal infections.

C. difficile causes a spectrum of illnesses ranging from antibiotic-associated diarrhea to pseudomembranous colitis. Patients usually present with diarrhea, abdominal cramps, and fever. Other common features include abdominal tenderness to palpation and dysenteric stools, although asymptomatic infections and mild acute gastroenteritis also have been reported. C. difficile gastroenteritis most often occurs in hospitalized patients, with onset during hospitalization or within 60 days after antibiotic therapy. The organism is ubiquitous and transmitted by fecal-oral contamination. Asymptomatic infants can be colonized with the organism. The disease is thought to be brought on by the change in the gut flora as a result of antibiotic administration. Incubation time is unknown. The presence of pseudomembranes and friable rectal mucosa are characteristic. C. difficile toxin in the stool is diagnostic. Stopping the offending agent and adding therapy with metronidazole (30 mg/kg/day, divided, five times daily) or vancomycin (40 mg/kg/24 hours, divided, five times daily) for 7 to 10 days are indicated.

Ingested C. perfringens organisms produce an enterotoxin during sporulation in the gut that causes fluid collection in ileal loops and diarrhea. The result is a short-lived illness characterized by watery diarrhea, moderate to severe abdominal cramps, midepigastric pain, and an absence of fever. Vomiting is uncommon. Food source contamination, often from catered food services, is the usual source of outbreaks. The incubation time is 6 to 24 hours. Diagnosis is made by finding high spore counts in the stool; no specific treatment is required.

S. aureus produces the archetypal food poisoning from ingesting preformed enterotoxin, usually from contaminated food. Onset of symptoms is within hours of exposure. The illness is short-lived and self-limited. Nausea, vomiting, abdominal cramps, and diarrhea with a notable absence of fever constitute the typical pattern.

V. cholerae is an Asian-African organism that also is seen in South America. Most cases occur in travelers returning from endemic areas. A unique strain is endemic to the Gulf Coast of the United States. The disease is acquired through ingestion of
tion of contaminated water and food, such as undercooked shellfish and raw vegetables. Because a large inoculum is required, person-to-person transmission does not occur. Diarrhea is caused by a heat-labile enterotoxin that increases cyclic adenosine monophosphate (cAMP) through adenyl cyclase, resulting in inhibition of sodium reabsorption with chloride and fluid secretion into the gut. Antibiotic treatment should be considered for patients with moderate to severe diseases. Susceptibility testing is recommended because of changing resistance patterns.

*Vibrio parahaemolyticus* is commonly found in seawater, shellfish, and fish. Illness most commonly is associated with ingestion of contaminated raw or undercooked seafood. Diarrhea, abdominal cramps, and nausea are common, whereas vomiting, headache, fever, and chills are less common. The disease usually is self-limited and does not require treatment with antimicrobials.

*E. coli* is part of the normal flora in the lower GI tract. Several types within this species are recognized to cause disease. *E. coli* is identified by distinct groups of either somatic or flagellar antigens that determine virulence properties. The enterotoxigenic *E. coli* (ETEC) strain produces heat-stable and heat-labile toxins and colonization factor, which are important mediators of the illness called *traveller’s diarrhea*. Travelers of all ages can be affected. The enteroinvasive *E. coli* (EIEC) strain is closely related antigenically and biochemically to *Shigella* species and causes a similar dysenteric illness. This form affects mostly adults and is often food-borne. The enteropathogenic *E. coli* (EPEC) strain is responsible for sporadic and endemic diarrhea in infants. This form does not produce toxins. The enterohemorrhagic *E. coli* (EHEC) strain, with *E. coli* O157:H7 being the prototype, produces bloody diarrhea without fever and is associated with the Shiga toxin. *E. coli* O157:H7 colonizes the lower GI tract in cattle and is an important cause of epidemics of bloody diarrhea and sometimes, hemolytic uremic syndrome (HUS).^6^ Controversy exists regarding indications for antibiotic treatment for *E. coli* diarrhea: Although such therapy may shorten the course in selected cases, it may be associated with increased risk for developing HUS^7^ in cases of diarrhea caused by O157:H7. Although a meta-analysis failed to confirm the increased risk,^8^ it is prudent to withhold antibiotics in diarrhea caused by EHEC.

Acute diarrheal illnesses in chronically ill and immunosuppressed patients often are due to the previously described agents, although they can be caused by several unusual organisms. In patients with acquired immunodeficiency syndrome, these infections may be acute, chronic, or recurrent and difficult to treat. Unusual organisms may include *Mycobacterium avium*, *Cryptosporidium*, cytomegalovirus, and adenovirus. Because of frequent antibiotic exposure, infections caused by *C. difficile*, *Candida albicans*, and *Pseudomonas aeruginosa* are more common in immune-suppressed patients.

**Clinical Features**

**Diagnostic Findings.** Although acute diarrhea in children often can be managed at home, it can cause significant fluid and electrolyte disorders. Indications for medical evaluation of children with diarrhea have been proposed.^9^ Serious illnesses may be overlooked on cursory examination. The principal goal of the ED evaluation is to identify the fluid, electrolyte, acid-base, or nutrient deficits that may result from vomiting, diarrhea, or decreased oral intake. It often is difficult to quantify the volume of diarrhea from the history. Helping the parent describe the stool relative to usual bowel habits may provide valuable information. The history should include specific information regarding the order of presentation, duration, and severity, and quantity if applicable, for each symptom. The clinician should solicit the presence or absence of fever, nausea, vomiting, hematemesis, abdominal pain, diarrhea, and hematochezia. The consistency and content of stools are important. The relationship of symptoms to eating and drinking should be established. It is helpful to know whether other persons in the household have a similar illness and whether previous episodes have occurred. A history of travel to endemic or epidemic areas may provide important information. Quantity and time of recent oral intake and information about recent pre-illness weight can be helpful. Information about orthostatic symptoms and the patient’s activity level is desirable.

The physical examination should include close scrutiny of the vital signs, while keeping in mind that clinical signs are often insensitive and nonspecific for dehydration.^10^ For example, tachycardia is sensitive but nonspecific, because there are many other causes of tachycardia such as fever and anxiety. On the other hand, hypotension is specific but insensitive, because children usually will maintain adequate blood pressure until severe intravascular depletion occurs. Capillary refill time and respiratory pattern are useful parameters to assess. Older children and adults may manifest symptoms at a lesser degree of volume depletion because of relatively smaller total body water and extracellular fluid volume. Important areas to emphasize with parents are addressed in Table 171-1.

**Complications.** The complications of acute diarrheal illness are reflected primarily in abnormalities of fluid, electrolytes, and acid-base status and in the systemic involvement from the infection. Hypoglycemia and metabolic acidosis are common in younger children yet manifest with nonspecific signs and symptoms. To inexperienced eyes, children may appear to

| Table 171-1 Clinical Assessment of Degree of Dehydration |

†Not usually indicated in mild or moderate dehydration.

compensate well, only to sometimes undergo rapid decompensation. With severe illness or illness superimposed on underlying chronic conditions, children may arrive at the ED in extremis. Children may present in frank shock with lethargy, weakness, respiratory distress, anuria, cardiac dysrhythmia, seizures, or coma. It is vital to recognize early signs of shock, such as persistent tachycardia, hyperpnea, irritability, and lethargy, and to restore intravascular volume prior to decompensation.

**Diagnostic Strategies.** In children assessed to have significant dehydration from acute gastroenteritis, serum electrolytes and glucose should be assessed. Although not indicated in most cases of uncomplicated acute gastroenteritis, stool samples should be obtained for culture if specific therapy, hospitalization, or infection control measures may be indicated. Stool cultures also may be helpful if the patient has systemic involvement or underlying chronic medical complications or if the illness involves dysenteric features. In immunosuppressed patients and infants younger than 2 to 3 months of age or with possible bacteremia, a complete blood count, stool studies, and blood and other cultures are indicated. The stool study of primary utility in the ED evaluation is microscopic analysis for leukocytes and occult blood to differentiate dysentery from acute gastroenteritis. The presence of fecal leukocytes (more than 5 per high-power field) or blood indicates that the offending organism has crossed the mucosal barrier and that the risk of invasiveness has increased. Nearly 90% of children with acute diarrhea caused by *Salmonella* or *Shigella* organisms will have fecal leukocytes in the stool. Fecal leukocytes are also found in patients with *Campylobacter* organisms, *Y. enterocolitica*, invasive *E. coli*, and *V. parahaemolyticus*. Other studies such as stool electrolytes, fecal fat, culture, ova, and parasites are of greater interest and may be of help in follow-up management by the child’s primary care physician. Stool culture, enzymelinked immunoassay for rotavirus, and other tests are indicated in patients who have not responded in the expected manner or in whom the illness is of prolonged duration (more than 2 weeks) or has dysenteric features. Additional studies also are indicated if it is necessary to identify a cause for a community outbreak. Liver enzymes, bilirubin, and hepatitis serologic studies will be useful to identify the cause of hepatitis. Urinalysis can provide an indication of hydration, the presence of urinary tract infection, hepatitis, and potential renal injury.

**Differential Considerations.** Vomiting in children is a very common sign with an exhaustive list of causes. Young children have no social embarrassment or the personal distaste for vomiting (or diarrhea or crying) that often forces adults to bear the relative discomfort of the symptom. Children may vomit in response to pain, anxiety, or fear, as well as to other usual causes of nausea. Some general causes of vomiting are presented in Table 171-2. Diarrhea also is a common reason for parents to bring their children to the ED. Most often, diarrhea is associated with other features of acute gastroenteritis, but it may be the sole presenting complaint. Table 171-3 presents a brief list of causes of diarrhea in children. An important point is that although most children with diarrhea or vomiting, or both, have a relatively benign cause for their illness, other, more sinister, diagnoses should be considered in appropriate clinical settings.

Appendicitis is the most common surgical condition in children and adolescents. The signs and symptoms are notoriously variable. The presence of vomiting and diarrhea does not necessarily rule out the diagnosis of appendicitis, especially when the child has abdominal pain. Intussusception is another diagnosis to consider in a young child with vomiting and abdominal pain, with or without bloody stool. Bilious vomiting in a child should raise concern for intestinal obstruction, such as from midgut volvulus. Enterocolitis can be the presenting manifestation, as well as a subsequent serious complication, of Hirschsprung’s disease. HUS is a rare but potentially fatal complication of enterocolitis caused by *E. coli* O157:H7 and *Shigella*.

**Management.** In addition to resuscitating children in shock, the priorities in ED management of children with diarrhea are (1) to consider other potential causes of diarrhea other than infectious diarrhea, (2) to assess for and treat underlying deficits and potential complications, and (3) to arrive at a microbiologic diagnosis. Table 171-4 lists the common infectious agents of diarrhea and the indicated treatment. Antidiarrheal compounds that impair GI motility, such as loperamide (Imodium), diphenoxylate, and atropine (Lomotil), have no role in the treatment of acute infectious diarrhea in young children, because they may prolong and exacerbate the disease and are potentially toxic.

**Disposition**

Most cases of childhood diarrhea can be managed on an outpatient basis by continuing routine formula or diet specific for age. Supplemental maintenance electrolyte solutions may be given. If home oral rehydration therapy is ordered, feeding

should resume as soon as vomiting subsides. Routine fasting for diarrhea illnesses is not recommended. Before discharge from the ED, careful and specific instruction regarding the signs and symptoms of expected improvement or complications must be given to the parents or caregiver (Box 171-1). Instructions should address proper hygiene and hand-washing techniques to prevent others from contracting the illness. Monitoring hand washing in daycare facilities has been shown to reduce bacterial contamination in children. Follow-up by the patient’s primary care physician should be timely and should address concerns of worsening of the condition and complications that may have developed. Hospitalization may be warranted in cases of protracted vomiting, diarrhea with losses in excess of fluid administration, worsening clinical status despite therapy, presence of an underlying condition that would complicate therapy, or suspected systemic involvement. Very-low-birth-weight infants, because of low physiologic reserve and immature immune system, are at the highest risk for complications of acute gastroenteritis in the first year of life.

DEHYDRATION

Clinical Features

Dehydration, or decrease in total body water, can be caused by a variety of mechanisms. Broadly speaking, however, mechanisms of dehydration comprise three general categories: decreased intake, such as with stomatitis; increased output, such as with diarrhea and diabetes; and increased insensible losses, such as with fever. The severity of dehydration usually is measured as the acute weight (presumably fluid) loss as a percentage of preillness total body weight. More than 5% dehydration is considered significant and often can be identified by history and physical examination (see Table 171-1). Because preillness weights generally are not available, the clinician will need to rely on historical information, physical examination, and laboratory tests in assessing the severity of dehydration. Parental reports of history and observation are of significant value, with good sensitivity in detecting dehydration.11 In a child who is dehydrated, initial physical exam may reveal an activity level lower than expected for age. The child may appear weak or lethargic. If the fontanel is still open, it may become less active or difficult to arouse. 

1. Give clear liquids, as much as the child wants.
   a. Children younger than 2 years of age should be given a maintenance electrolyte solution, such as Pedialyte or Infalyte.
   b. Children older than 2 years of age may be given other clear fluids, such as decarbonated sodas, Gatorade, or clear soups.

2. If your child is vomiting, give clear liquids (as above) in small frequent volumes initially and advancing to normal volumes for the child’s age as tolerated. It may be necessary to use teaspoons, cups, syringes, or ladles to administer the small volume. Fluid can be administered beginning 5 to 10 minutes after an episode of vomiting and should be continued despite the persistence of vomiting.

3. The child’s diet may be advanced as soon as the vomiting has stopped and the child can tolerate fluids without vomiting. It is reasonable to wait 2 hours after the last episode of vomiting to resume feeding.
   a. Formula- or breast-feeding infants should be given their regular formula or returned to the breast.
   b. Older children should be given bland, starch-containing foods (bananas, rice, applesauce, and toast make up the popular “BRAT” regimen) in small quantities first and advancing to larger quantities and more complex items as the child’s appetite returns.

4. The child may return to a regular diet as soon as the appetite returns and foods are desired.

5. Many foods may worsen diarrhea; pectin-containing foods, such as applesauce and other fruits and fruit juices, are not recommended until the diarrhea resolves.

6. Reduce the amount of cow’s milk products in the diet until the diarrhea has lessened significantly.

7. Call your child’s physician or return to the emergency department if any of the following occurs:
   a. The diarrhea or vomiting worsens in frequency or amount.
   b. The vomiting lasts for more than 24 hours.
   c. The stool or vomitus contains blood or the vomit becomes persistently green.
   d. The child has decreased urine output (not as many wet diapers), does not produce tears when crying, or becomes less active or difficult to arouse.
tremia) or a doughy texture (suggesting hypernatremia) (Table 171-5). It is important to keep in mind that clinical signs and symptoms of dehydration are variable and often subtle.

Use of laboratory tests may be helpful in assessing children for etiology, severity, and complications of dehydration. A serum electrolyte panel and blood urea nitrogen (BUN), serum creatinine, and blood glucose determinations are the tests most commonly ordered. Sodium concentration is important in identifying iso-, hypo-, or hypernatremic states for appropriate choice of therapy. A low serum HCO₃⁻ level may indicate loss of HCO₃⁻ in the stool or may reflect poor tissue perfusion. Newer noninvasive techniques for detecting dehydration have been described, such as ultrasound assessment of inferior vena cava diameter and measurement of exhaled CO₂ as a marker for acidosis. Children with dysentery should have BUN and serum creatinine measured and stool examined for E. coli O157:H7 to identify potential cases of HUS. Serum glucose level is important, because hypoglycemia is common in young children with viral gastroenteritis, and this test may help identify children with previously undiagnosed fatty acid oxidation disorders or other inborn errors of metabolism. Diabetes mellitus may manifest with vomiting and dehydration. In some cases it may be necessary to examine urine electrolytes and osmolality.

### Differential Considerations

Most commonly, dehydration in children results from diarrhea and vomiting caused by infectious gastroenteritis. Table 171-6 lists some other causes of dehydration that should be considered when the GI tract is not primarily involved.

### Fluid and Electrolyte Management

#### Oral Rehydration Therapy

Oral rehydration therapy (ORT) is a safe and effective treatment for infants and children with mild to moderate dehydration. ORT may be instituted even if the patient continues to vomit or has diarrhea. Children with severe dehydration, shock, lethargy, acute abdomen, suspected intestinal obstruction, sodium derangement, or significant underlying illness should be identified by means of a thorough history and physical examination and laboratory tests and be excluded from ORT. Some of these principles are illustrated in Box 171-2.

The ORT period in the ED may span 4 to 8 hours and provides an opportunity to educate the family in skills of evaluating and treating childhood diarrhea. A number of oral rehydration solutions (ORSs) have been shown to be effective. The main ingredients are water, glucose, sodium chloride, and bicarbonate in various concentrations (Table 171-7). Rehydration is an excellent initial solution for children with viral gastroenteritis. The volume of ORS is calculated in the following manner:

1. Estimate the degree of volume depletion as mild or moderate using information from the history, clinical signs, and physical examination.

*May be long-chain oligosaccharide subject to hydrolysis.
WHO, World Health Organization.

2. Calculate the desired volume of ORS as 60 mL/kg for mild and 80 mL/kg for moderate volume depletion.
3. Administer 25% of the volume of ORS to be replaced each hour for the first 4 hours.
4. Monitor progress hourly and reevaluate after 4 hours.

This technique requires that the ED have the facilities and personnel to observe and monitor the patient for the 4 to 8 hours necessary to determine the success or failure of ORT. The parent or other caregiver can be taught to administer ORT. Nursing personnel also should instruct the parent in observation skills, methods of administering the fluid, and types of fluid that are considered appropriate for children with vomiting and diarrhea. During the monitoring period, a child who is unable to tolerate intake of the prescribed volume of fluid at the expected rate should receive intravenous fluids. It is important to determine and address whether the failure is the result of the child’s inability to ingest the fluid, excessive fluid loss through vomiting or diarrhea, or poor technique or motivation on the parent’s part. It usually is possible to maintain the fluid administration rate in children who continue to vomit by administering small volumes frequently. This may require, for instance, using a spoon or syringe to slowly drip the fluid by hand. Some success has been obtained with the use of nasogastric tubes. Emesis (volume-for-volume) and stool volume (5 mL/kg) losses are estimated and these amounts added to the replacement volume on an hourly basis. The patient is reassessed at the end of the first 4 hours. If the clinical examination indicates adequate volume repletion, the child may be discharged home with further specific instructions for parents regarding maintenance fluid requirements. If, on the other hand, the child still exhibits mild or moderate volume depletion on clinical examination but no deterioration in status has occurred, the child is reevaluated as if from the beginning, and another 4-hour trial is attempted. If the child is unable to ingest the appropriate volume, or if volume repletion is not achieved at the end of 8 hours, intravenous therapy should be initiated.

Patients are evaluated in accordance with their immediate (emergency phase, phase I), short-term (repletion phase, phase II), and long-term (early refeeding phase, phase III) needs. During the emergency phase, the aim of fluid resuscitation is to restore circulatory volume. This fluid needs to be administered rapidly to prevent imminent serious morbidity or death. During the repletion phase, fluid and electrolyte derangements are reversed, and ongoing losses are replaced. This phase lasts 24 hours. In the early refeeding phase, long-term needs are addressed over the next few days, during which the body recovers fluid, electrolyte, and nutritional homeostasis. Immediate and short-term therapies are initiated in the ED, with subsequent phases carried out in the inpatient setting or at home as managed by the primary care physician. In clinical practice, this algorithm represents a continuum of care and not three distinct, separate phases. Monitoring of serum electrolytes, BUN, and blood glucose is indicated for patients receiving intravenous fluid therapy.

Emergency Resuscitation Phase

Rapid reexpansion of the intravascular space is the goal of immediate resuscitation and can be achieved with an isotonic crystalloid solution. Administering 20 mL/kg of 0.9% saline (or other appropriate isotonic crystalloid solution) IV at a rapid rate should result in reversal of signs of shock within 5 to 15 minutes. In critical situations, interosseous routes should be used if venous access is not immediately available. Patients should be reevaluated periodically, and those with excessive deficits should receive repeat boluses of 20 mL/kg until clinical improvement occurs. Signs of recovery include normalization of blood pressure measurements, improvement of mental status, and production of urine. Volume requirements greater than 60 mL/kg without signs of improvement warrant investigation for other conditions, such as septic shock, hemorrhage, capillary leak with third space fluid sequestration, congestive heart failure, and toxic shock.

A rapid determination of serum glucose is important. Children require glucose as an energy substrate and often have marginal stores available in illnesses. If the serum glucose is low (less than 50 mg/dL), rapid administration of dextrose 0.25 to 0.5 g/kg IV (in neonates younger than 3 months of age, 10% dextrose at 2 to 5 mL/kg is used) should correct the deficit. Glucose levels should be monitored (every 30 to 60 minutes until stable) to ensure improvement and to identify ongoing needs. Repeated episodes of hypoglycemia should raise sus-
picion for fatty acid oxidation defects and other inborn errors of metabolism.

Repletion Phase
After immediate resuscitation, appropriate fluid therapy for the patient should be determined. Calculations should take into account the fluids already administered and also should accommodate changes in the patient’s clinical status. To allow accurate planning of the type and amount of fluid to be administered, volume replacement should proceed from the serum sodium level: hypernatremia (serum sodium level greater than 150 mEq/L), hyponatremia (sodium level less than 130 mEq/L), or isonatremia (sodium level of 130 to 150 mEq/L).

Isonatremic Volume Depletion
Isonatremic volume depletion is the most common form of volume depletion and results from relatively equal losses of sodium and water. No change in body fluid tonicity or redistribution of fluid between the extracellular and intracellular fluid spaces occurs. This results in loss of fluid from the extracellular space and, therefore, intravascular volume depletion. GI fluid loss with or without decreased intake or increased urine loss is the most common cause. Repletion fluids are outlined for a sample patient in Box 171-3. Generally, one half of the deficit fluids is given during the first 8 hours of repletion.

Note that the sample patient is mildly acidic (HCO$_3^-$ greater than 12 mEq/L) and that restoring intravascular volume results in improved tissue perfusion and correction of the metabolic acidosis. These calculations account for water and electrolyte requirements (maintenance and deficit) and demonstrate that use of a standard fluid preparation (0.9%, 0.45%, or 0.2% saline) permits close approximation of calculated requirements and facilitates treatment by relying on readily stocked supplies.

**Notes**
1. Fluid resuscitation is crucial during phase I. If initial response is poor, additional infusions are warranted. Generally, the initial emergency fluid bolus should be included as part of the deficit replacement.
2. Blood glucose should be assessed early, especially in children with prolonged vomiting, diarrhea, or inadequate intake. Early glucose infusion may be warranted.
3. If the patient is acidic with HCO$_3^-$ of ≤10 mEq/L or a pH < 7.1 on the basis of metabolic acidosis, one third of the sodium may be administered as NaHCO$_3$.
4. In the face of acidosis, serum potassium does not reflect total body deficit.
5. Adjust for fever (add 10% for each 1°C over 37°C), stool loss (5 mL/kg), or vomiting (volume for volume).

D$_5$W, 5% dextrose in water; ECF, extracellular fluid; ICF, intracellular fluid; NS, normal saline; RL, Ringer’s lactate.

Hyponatremic volume depletion is a result of loss of relatively more sodium than water, resulting in extracellular water shift into the intracellular fluid space to maintain equal osmolarity. This results in a significant decrease in intravascular volume and hemodynamic compromise. This type of volume deple-
tion usually is caused by GI fluid loss that has been replaced with hypotonic fluid. Specific signs and symptoms of hypona-
tremia are largely neurologic, ranging in severity from malaise and irritability to seizures and coma.

Appropriate management of hyponatremic dehydration for a sample patient is described in Box 171-4. If the serum sodium is 120 to 130 mEq/L, 5% dextrose in 0.9% saline is admin-
istration of hypotonic fluids.

### Sample Calculation of Fluid and Electrolyte Requirements in a Patient with Hyponatremic Volume Depletion

#### Initial Findings
- **Preillness weight:** 10 kg (a 1-year-old)
- **Degree of volume depletion:** moderate (10%)
- **Body weight on admission:** 9 kg
- **Electrolytes:**
  - Na⁺ 110 mEq/L
  - K⁺ 5 mEq/L
  - Cl⁻ 90 mEq/L
  - HCO₃⁻ 12 mEq/L

#### Sodium Deficit Calculation

A. Na⁺ required to correct to 135 mEq/L = 135 mEq/L – 110 mEq/L (observed Na⁺) = 25 mEq/L

B. Total body water (TBW) (L/kg) = 0.6 L/kg (preillness TBW) – 0.1 L/kg (water loss) = 0.5 L/kg

C. Preillness weight = 10 kg

Sodium deficit = A × B × C = 25 mEq/L × 0.5 L/kg × 10 kg = 125 mEq

#### Notes

1. Fluid resuscitation is crucial during phase I. If initial response is poor, additional infusions are warranted. Generally, the initial emergency fluid bolus should be included as part of the deficit replacement.
2. If a patient is acidic with HCO₃⁻ of ≤10 mEq/L or a pH ≤ 7.1 on the basis of metabolic acidosis, one third of the sodium may be administered as NaHCO₃.
3. In the face of severe hyponatremia with decreased TBW in symptomatic patients, hypertonic 3% saline must be given to raise the serum sodium level to 125 mEq/L. A 3% saline solution contains approximately 0.5 mEq Na⁺/mL. Patients may be given 3% saline 4 mL/kg IV over 10 minutes and the response monitored. Once seizures have stopped, half of the deficit may be corrected over the next 8 hours as outlined in the fluid schedule.
4. If excess water load is the cause, furosemide (Lasix) 1 mg/kg/dose IV may be used. During the subsequent diuresis, urinary sodium, potassium, and chloride should be measured and replaced milliequivalent for milliequivalent with 3% saline and supplemental potassium chloride.
5. Blood glucose should be assessed early, especially in children with prolonged vomiting, diarrhea, or inadequate intake. Early glucose infusion may be warranted.
6. In the face of acidosis, serum potassium does not reflect total body deficit.
7. Adjust for fever (add 10% for each 1° C over 37°C), stool loss (5 mL/kg), or vomiting (volume for volume).

tered, with one half of the daily fluid requirement given in the first 8 hours and the remainder over the succeeding 16 hours. Monitoring of serum electrolytes, BUN, weight, and intake and output is recommended. Rapid correction of hyponatremia can be associated with central pontine myelinolysis. Close monitoring of serum sodium is indicated to avoid correcting by more than 1 mEq/L per hour. Potassium chloride, 20 mEq/L, is added to the intravenous fluids after renal function is assessed. If the serum sodium is less than 120 mEq/dL, the patient will exhibit seizures, hyperexcitability, or other neurologic symptoms. In such cases, 3% saline (0.5 mEq sodium chloride/mL) should be administered according to the following formula:

\[
3\% \text{ saline (mL)} \times (10 \text{mEq/L}) \times (0.6) (\text{weight})/0.5)
\]

Avoiding too-rapid correction of serum sodium is warranted because of the risk for central pontine myelinolysis, as noted. This disorder has been reported in children, especially those undergoing fluid resuscitation for hyponatremic dehydration in diabetic ketoacidosis.17,18 In some conditions causing hyponatremia, furosemide (1.0 mg/kg IV) or other diuretics have been recommended. The mechanism of action of the loop diuretics must be considered, because free water is excreted with an obligatory solute (sodium) loss. Diuretics may be used in combination with saline administration in an attempt to avoid sodium depletion.

Hyponatremic dehydration must be differentiated from another common cause of hyponatremia, the syndrome of inappropriate ADH secretion (SIADH). In this syndrome, caused by a variety of conditions, the kidneys inappropriately excrete sodium and retain water, resulting in low serum sodium and high urinary sodium concentrations. Treatment is with fluid restriction.

**Hyponatremic Volume Depletion**

Hyponatremic volume depletion arises with loss of relatively more water than sodium. It can occur if inappropriate types of fluids are given, if the fluid or formula is mixed incorrectly, or if fever or hyperventilation complicates the illness. This is the least common type of volume depletion because of a generally lower content of sodium in most modern infant fluids and formulas. Intracellular water shifts to the extracellular fluid space to maintain osmolar balance; therefore, intravascular volume is relatively preserved. Signs and symptoms specific to hyponatremia are “doughy” skin and altered CNS function (manifested as irritability, seizures, or high-pitched cry). Care must be taken not to administer hypotonic fluid at too fast a rate, because water will equilibrate across the cerebral blood-brain barrier almost immediately (long before the sodium is corrected), creating increased intracranial pressure. This type of dehydration should be corrected over 48 to 72 hours. Box 171-5 provides guidelines for the calculation of fluids and electrolytes for a sample case. Close monitoring of neurologic status and serum electrolytes is important during the period of rehydration.

**Hospital-Acquired Hyponatremia**

One of the complications that can develop during intravenous rehydration in children is acute hyponatremia. In children, this rare disturbance can lead to significant neurologic morbidity, including seizures, coma, and brain herniation, or even death. For acute hyponatremia to occur, two conditions have to be met: (1) an exogenous source of free water must be available, and (2) secretion of ADH must occur. Many experts, therefore, recommend using isotonic saline, rather than hypotonic saline, as the replacement intravenous fluid of choice in hospitalized children.19,20 This practice is not universally accepted.21 In any case, vigilance in monitoring the neurologic status of children undergoing intravenous rehydration is essential.

---

**BOX 171-5**  **HYPTERTONIC DEHYDRATION**

A 2-week-old infant presents to the ED with a history of 1 day of poor breast milk intake. Weight yesterday at a well-baby visit was 4 kg; today the child weighs 3.4 kg. Laboratory study findings include serum Na⁺ 155 mEq/L; K⁺ 4.5 mEq/L; HCO₃⁻ 13 mEq/L.

**Maintenance Therapy**

100 mL/day for first 10 kg = 400 mL

Na⁺ requirements = 3 mEq/kg × 4 kg = 12 mEq

K⁺ requirements = 2 mEq/kg × 4 kg = 8 mEq

**Total Fluid Deficit: 4.0 – 3.4 = 0.6 L**

Free water deficits = observed Na⁺ – ideal Na⁺ (145 mEq/L)] × 4 mL/kg × wt (kg) = (155 – 145) × 4 mL/kg × 4 kg = 160 mL

**Na⁺ Deficit**

The illness is less than 3 days in duration. Therefore, the fluid lost is 75% from the ECF and 25% of the ICF. Primary sodium reservoir is ECF.

**Na⁺ loss** = (ECF Na⁺ concentration) × (75% of solute fluid deficit) = (140 mEq/L) × (0.75 × 0.440L) = 46 mEq

**K⁺ Deficit** (Primary Potassium Reservoir is ICF):

**K⁺ loss** = (ICF K⁺ concentration) × (25% of solute fluid deficit) = (150 mEq/L) × (0.25) × 0.440L = 16 mEq

**48-Hour Requirements = Maintenance + Deficits**

**Total deficits:**

Fluid (mL) = (400 × 2) mL + 160 mL (free) + 440 mL (solute) = 1400 mL

Sodium (mEq) = 24 + 46 = 70 mEq

Potassium (mEq) = 16 + 16 = 32 mEq

**Fluid Schedule**

The fluid is administered in a step-wise fashion over 48 hours. One half the deficit is given in the first 24 hours; then the remainder is given over the next 24.

**First Day Fluids = Maintenance + ½ Deficits**

First day fluids = (400 mL + 12 mEq Na⁺ + 8 mEq K⁺) + ½ (600 mL + 46 mEq Na⁺ 16 mEq K⁺)

First day fluids = 700 mL D₂W + 35 mEq Na⁺ + 16 mEq K⁺

In practice (and after the calculations are done), the usual fluid that is required to rehydrate the child with hypertonic dehydration is either D₂W 0.2% NS or D₂W 0.45% NS, because it would appear that the rate rather than the volume of fluid is most important. The volume of free water needed to lower a serum sodium concentration above 145 mEq/L is approximately 4 mL/kg of free water for each 1 mEq/L over 48 hours.

Studies demonstrate that D₂W, D₂W 0.2% NS, and D₂W 0.45% NS all are acceptable if infused at a conservative rate, correcting deficits over 48 hours.

D₂W, 5% dextrose in water; ECF, extracellular fluid; ICF, intracellular fluid; NS, normal saline; RL, Ringer’s lactate.

*Calculated as (600 mL fluid deficit – 160 mL free water deficit).
KEY CONCEPTS

- **Identification of pathogen**: Stool studies are not indicated in most uncomplicated cases of acute gastroenteritis. Exceptions are those cases in which specific treatment, specific prophylaxis, or health precautions are required or in which the patient has systemic involvement or underlying medical complications or the illness involves dysenteric features.

- **Fecal leukocytes**: The presence of fecal leukocytes or blood indicates that the offending organism has crossed the mucosal barrier and that the risk of invasiveness has increased. Nearly 90% of patients with acute diarrhea caused by *Salmonella* or *Shigella* organisms will have fecal leukocytes in the stool.

- **Oral rehydration**: With oral rehydration therapy, resumption of feeding should begin as soon as vomiting subsides. Routine fasting with infectious diarrhea is not recommended. Patient and family instruction should address proper hygiene and hand-washing techniques to prevent others from contracting the illness.

- **Dehydration assessment**: The degree of volume depletion is estimated using information from the history, clinical signs, and physical examination. The desired volume of oral rehydration solution (ORS) is calculated as 60 mL/kg for mild and 80 mL/kg for moderate volume depletion; then 25% of the volume of ORS to be replaced is administered each hour for the first 4 hours.

- **Severe dehydration**: In severe dehydration, 20 mL/kg of 0.9% saline (or other appropriate isotonic crystalloid solution) given IV at a rapid rate should result in reversal of signs of shock within 5 to 15 minutes. Repeat boluses of 20 mL/kg are indicated until clinical improvement occurs, but volume requirements greater than 60 mL/kg without signs of improvement suggest other conditions, such as septic shock, hemorrhage, capillary leak with third space fluid sequestration, and heart failure.

**Chapter 172** Genitourinary and Renal Tract Disorders

Maureen McCollough and Ghazala Q. Sharieff

---

**PERSPECTIVE**

This chapter discusses some of the more common causes of scrotal, testicular, and penile pain in children that precipitate a visit to the emergency department (ED). Also discussed are other renal or genitourinary tract disorders in this age group for which emergent treatment may be sought, including acute renal failure, urinary tract infections, and hypertension.

---

**SPECIFIC DISORDERS**

**Penile Disorders**

**Priapism**

**Principles of Disease.** Priapism is the engorgement of the dorsal corpora cavernosa, resulting in dorsal penile erection and ventral penile flaccidity. Sickle cell disease and leukemia are responsible for a majority of cases in children. Spinal trauma, immunosuppressive disorders, anticoagulation, and intracavernosal injection of agents such as papaverine, phenolamine, and prostaglandin-E1 also can result in priapism. Other drugs such as phenothiazines, sedative-hypnotics, selective serotonin reuptake inhibitors, antihypertensives, anticoagulants, and drugs of abuse (e.g., cocaine, alcohol, marijuana) may be causal.

The more common low-flow priapism is secondary to decreased venous outflow and is characterized by prolonged painful erection. High-flow priapism usually is painless and typically is associated with penile arterial laceration and excessive inflow of arterial blood, resulting in corporal engorgement. With prolonged engorgement of the corpora cavernosa, the resultant stagnation and hypoxia of the blood lead to the development of thrombosis and ischemia. Priapism complications include penile fibrosis, urinary retention, and impotence.

**Clinical Features.** Priapism is a clinical diagnosis and can be distinguished from other causes of erection by careful history and complete physical examination. The history should include past medical history with attention to previous treatment for anemia, leukemia, sickle cell disease, or drug abuse and current history of trauma or symptoms of immunosuppressive disease. Physical examination should be extensive and look for rash, lymphadenopathy, pale or jaundiced skin, or signs of a toxidrome. Although, as noted, priapism is a clinical diagnosis, laboratory studies may assist in isolating the cause of the condition. A complete blood count (CBC), hemoglobin electrophoresis, and coagulation studies may be useful in some cases. Diagnostic studies of penile blood flow may be indicated in cases for which the cause is unclear and may include magnetic resonance imaging (MRI), color Doppler cavernosonography, and technetium-99m penile scanning. Angiography is helpful in localizing the arterial bleeding site in high-flow priapism.1

**Differential Considerations.** The differential diagnosis for priapism in children differs from that in adults. In adults, penile erection from sexual arousal, urethral foreign bodies, Peyronie’s disease, spinal cord injury, and penile implants may occur, but these etiologic factors would be rare in children. Anticoagulation, drugs of abuse, medications, trauma (including spinal trauma), Kawasaki disease, leukemia, and sickle cell disease all are associated with priapism in children.

**Management and Disposition.** Management centers on hydration, pain control, relief of urinary obstruction, and treatment of any other underlying conditions. Local anesthesia effected by dorsal nerve block using 1% lidocaine without epinephrine may be beneficial. Infiltration with hyaluronidase also may be effective. In patients with sickle cell disease, treatment is begun with oxygen, hydration, and analgesics. Low-flow priapism may respond to sitz baths or hot compresses, because the heat increases blood flow, thereby potentially relieving the obstruction.

In addition, cavernosal aspiration plus irrigation has been effective in patients with low-flow priapism. This procedure should be performed within the first few hours of symptom onset and rarely is beneficial after 48 hours. Phenolamine, phenylephrine (100 to 500 µg per dose for up to 10 doses; 10 to 20 mL of 20 µg/mL of solution given by intracavernous injection every 5 to 10 minutes), ephedrine, or 1:1,000,000 epinephrine often is added to the irrigation solution used in performing corporal aspiration. Alternatively, mix 1000 µg of phenylephrine in 100 mL of isotonic sodium chloride solution (10 µg/mL) and infuse 10–20 mL at a time. Parenteral vasodilators such as papaverine, hydralazine, and terbutaline also have been tried, with variable success.2

Exchange transfusion previously has been recommended; however, this treatment may not offer any advantage over conventional therapy and has been associated with serious neurologic sequelae, as in the so-called ASPEN syndrome (association of sickle cell disease, priapism, exchange transfusion, and neurologic events).3,4 Patients with leukemia may respond with detumescence after chemotherapy is begun.

High-flow priapism in children is rare; accordingly, treatment modalities have not been well studied. High-flow states can be effectively addressed using arterial embolization. If
nonsurgical approaches are unsuccessful, a corpus cavernosa–
glans shunt procedure may be necessary. In a recent case
report, ultrasound-guided compression of the perineal arterio-
cavernous fistula was successful.\textsuperscript{3} Interventions should be ini-
tiated within 12 hours of symptom onset to avoid long-term
dysfunction and irreversible infarction.\textsuperscript{6} Patients with persist-
tent priapism or underlying disorders such as leukemia or
sickle cell disease require hospitalization. Pediatric urologic
consultation should be arranged as soon as possible. If the
priapism has been treated successfully, then after some period
of observation, the patient may be discharged home with uro-
logic specialist follow-up.

**Phimosis**

**Principles of Disease.** *Phimosis* is a pathologic condition of the uncir-
cumcised penis in which constriction of the foreskin prevents
retraction of the prepuce from over the glans. It can result in
pain, hematuria, and urinary outlet obstruction. Most cases are
physiologic, representing normal development, and do not
require intervention. Only 4\% of newborn males have a fully
retractable foreskin. This percentage increases with age: 25\% of
6-month-olds, 50\% of 1-year-olds, 80\% of 2-year-olds, and
90\% of 4-year-old boys have fully retractable foreskins.\textsuperscript{7} Phi-
mosis also may result from trauma, infections, chemical irrita-
tion, poor hygiene, congenital abnormality, or be a complication of
circumcision.

**Clinical Features.** Phimosis is a clinical diagnosis. History may
reveal that the foreskin is unretractable, along with narrowing
or diversion of the urinary stream and bulging out of the fore-
skin with urination. Pain and hematuria may be accompanying
features.

**Management and Disposition.** Because the ability to retract the
foreskin fully is age-related, parents should be advised not to
retract the prepuce forcefully. Gentle retraction with good
hygiene should be stressed. If signs of urinary outlet obstruc-
tion are present, dilation of the prepuce or the urethral meatus
or both can be performed by gentle use of forceps. With vas-
cular compromise of the glans, a dorsal split procedure, circum-
cision, preputial plasty, or balloon dilation may be necessary.\textsuperscript{3,9}
Topical steroid treatment (with betamethasone valerate 0.6%
cream) for 6 weeks has been 87\% effective in reducing inflam-
mation and treating phimosis.\textsuperscript{10,12} In patients with severe ste-
nosis, obstructive uropathy can result. In such cases, blood
urea nitrogen (BUN) and serum creatinine levels should be
obtained, and a renal ultrasound examination should be per-
formed if signs of obstructive renal failure are present. Patients
who are able to urinate and have no evidence of severe infec-
tion or ischemia can be discharged from the ED with outpa-
tient urologic follow-up.

**Paraphimosis**

**Principles of Disease.** *Paraphimosis* is another pathologic condition
of the uncircumcised penis in which the proximal foreskin
cannot be returned to its anatomic position covering the glans
penis, resulting in distal venous congestion with the potential
for dire consequences. Paraphimosis can be caused by infec-
tion, masturbation, trauma, or hair or clothing tourniquets.
Iatrogenic causes include failure to reduce the foreskin after a
medical examination. Paraphimosis constitutes a true urologic
emergency and can result in arterial compression, penile
necrosis, and gangrene.

**Clinical Features.** The patient typically is anxious, and the
history often reveals that the parents or the patient retracted
the foreskin and then could not replace the foreskin back over
the glans (Fig. 172-1). The history should include verification
that the patient is uncircumcised, because hair tourniquet syn-
drome in a circumcised patient may mimic paraphimosis.
Physical examination reveals a flaccid proximal penis with
erythema and engorgement distal to the obstruction. The fore-
skin is retracted, and cellulitis may be present. The diagnosis
of paraphimosis is based on clinical findings, but if a penile
foreign body is a concern, radiographs can be obtained after
relief of the vascular occlusion.

**Management and Disposition.** Pain can be controlled either paren-
terally or by performing a local dorsal penile nerve block. Pro-
cedural sedation also may be necessary. Placing a finger of a
rubber glove filled with ice water over the glans and foreskin
can reduce the edema. Circumferential compression of the
penis starting at the glans also can reduce the edema. Com-
pression may need to be held for several minutes to achieve
adequate reduction of edema. Manual reduction may be nec-
essary, with application of gentle, steady pressure on the glans
with both thumbs while the shaft is pulled straight (Fig. 172-
2). Another method is to puncture the edematous foreskin
with an 18- or 21-gauge needle.\textsuperscript{13,14} The puncture may be fol-
lowed by squeezing of the glans penis to further facilitate fluid
drainage. Dorsal band traction has been performed in some
cases by application of Adson forceps directly to the band
formed by the retracted foreskin and applying traction and

Complications of Circumcision

Principles of Disease. Circumcision usually is advocated for prevention of phimosis, paraphimosis, recurrent balanoposthitis, urinary tract infections, and penile cancer. Any of three techniques can be used: application of a Plastibell or Gomco clamp, excision, or a dorsal slit procedure. The choice of procedure is dependent on the preference of the operator. The most common complication of these procedures is hemorrhage, which usually is minor and can be controlled by direct pressure, silver nitrate application, or suture placement. Significant bleeding may be a sign of a blood dyscrasia. Localized, systemic, or urinary tract infection also can occur.

Management and Disposition. Postoperative pain usually resolves within 12 to 24 hours. Occlusive dressings can contribute to urinary retention and edema and should be removed. Stenosis of the now exposed urethral meatus may result from prolonged exposure to the ammonia in urine. Application of a Plastibell that is too small also can lead to meatal stenosis in 8 to 31% of cases.18 Signs and symptoms include pain with urination, bloody discharge resulting from inflamed meatus, high-velocity stream, and the need to sit while voiding. Postcircumcision phimosis may result if excess foreskin remains. If the constriction is severe and urinary outlet obstruction occurs, dilatation of the stenosis can be performed using a hemostat. Surgical revision usually is necessary.19

Skin bridges are small fibrotic bands that attach the glans to the penile shaft and may form after circumcision. Inclusion cysts result from smegma retained in the wound or from epidermis involution along the circumcision site. Like skin bridges, these are treated by surgical resection. These complications may be prevented by proper hygiene and application of an antimicrobial ointment to the circumcision site for 7 to 10 days after the procedure.

Penile Entrapment and Tourniquet Injuries

Penile rings, string, wire, and human hair tourniquets can result in penile venous and arterial occlusion. The patient presents with swelling of the glans, wherein the offending agent may be difficult to visualize because of edema of the coronal sulcus. In addition to the vascular supply, the dorsal penile nerve supply can be occluded. Urethral obstruction can be evaluated by means of a retrograde urothrogram, and Doppler ultrasonography can be performed to assess penile arterial blood flow. Once identified, the constriction is relieved, and the patient should not be discharged until spontaneous voiding is ensured. Urologic consultation may be necessary emergently if penile arterial flow is disrupted and the constricting object cannot be removed rapidly or signs of necrosis are present.

Zipper entrapment of the foreskin also can occur in children, typically those between 2 and 6 years of age. The zipper can be removed with bone or metal cutters or a mini-hacksaw to cut the median bar of the zipper.20,21 (Fig. 172-4). The zipper falls apart and the foreskin is freed. Although local anesthesia is not necessary, the patient may be quite anxious and require sedation before its removal. Success has been reported with soaking the penis in mineral oil before zipper removal.22 Additional methods to release the foreskin under the zipper mechanism include simply cutting the zipper below the entrapment and pulling the two halves of the zipper apart, cutting the zipper teeth above and below the entrapment and using pliers, squeezing the median bar to allow for more room to disengage the trapped prepuce, and inserting a flat screwdriver between the faceplates of the zipper mechanism to pry open the faceplates and allow the prepuse to be released.23-25 Parents should be instructed to encourage their children to wear underwear to decrease the risk of entrapment.
Tract infections, anatomic abnormalities, or previous genitourinary trauma. Patients may have a history of previous urinary tract infections leading to epididymitis typically are caused by viruses or bacterial agents, such as Chlamydia trachomatis. Color-flow Doppler ultrasonography or radionuclide scintigraphy will reveal a normal testis and preserved or increased vascular flow toward the side of the inflamed epididymis. Color Doppler ultrasonography should be performed in all children with suspected epididymitis and is the preferred diagnostic study because it does not require placement of an intravenous line and is more readily available at all hours of the day.

Management and Disposition. Scrotal elevation, placement of ice packs on the swollen area as tolerated, and nonsteroidal anti-inflammatory or narcotic medications are useful to control pain and inflammation. If urethral discharge is present, the adolescent patient should be treated for both N. gonorrhoeae and C. trachomatis. The preferred diagnostic study because it does not require placement of an intravenous line and is more readily available at all hours of the day.

Management and Disposition. Scrotal elevation, placement of ice packs on the swollen area as tolerated, and nonsteroidal anti-inflammatory or narcotic medications are useful to control pain and inflammation. If urethral discharge is present, the adolescent patient should be treated for both N. gonorrhoeae and C. trachomatis. The preferred diagnostic study because it does not require placement of an intravenous line and is more readily available at all hours of the day.

Management and Disposition. Scrotal elevation, placement of ice packs on the swollen area as tolerated, and nonsteroidal anti-inflammatory or narcotic medications are useful to control pain and inflammation. If urethral discharge is present, the adolescent patient should be treated for both N. gonorrhoeae and C. trachomatis. The preferred diagnostic study because it does not require placement of an intravenous line and is more readily available at all hours of the day.

Management and Disposition. Management and Disposition. Scrotal elevation, placement of ice packs on the swollen area as tolerated, and nonsteroidal anti-inflammatory or narcot...
epididymitis coexists, then a urethral discharge also may be present. Bacterial orchitis can result in scrotal abscess formation. Because orchitis typically is unilateral, fertility usually is maintained.

Doppler ultrasound imaging may be necessary to distinguish orchitis from testicular torsion. For patients with a clearly viral origin such as mumps, treatment is aimed at pain control (scrotal elevation, nonsteroidal anti-inflammatory agents, and possibly narcotics). When the diagnosis is unclear or when concurrent epididymitis is present, empirical treatment includes oral antibiotics with predominantly gram-negative organism coverage. Hospital admission is warranted for patients who have a toxic appearance or exhibit evidence of a scrotal or testicular abscess or in whom outpatient management has failed. Urologic follow-up should be arranged.

Testicular Torsion

Principles of Disease. Torsion of the spermatic cord is a common cause of an acutely painful scrotum. Delay in diagnosis and treatment can result in loss of spermatogenesis and, in severe cases, necrotic, gangrenous testes. Testicular salvage rates are time-dependent, with a 96% success rate if detorsion is performed less than 4 hours from symptom onset, decreasing to less than 10% if there is a greater than 24-hour delay to treatment.30 The overall incidence of testicular torsion is 1 in 4000, with a peak incidence at age 13 years. Testicular torsion has been reported in all age groups, from the developing fetus to the elderly, but is most common in adolescence.

The testis enters the scrotum through the inguinal canal after descent from the abdomen. The peritoneum invaginates through the canal and partially covers the testis and epididymis, forming the tunica vaginalis. Typically, the tunica vaginalis attaches to the posterior wall of the hemiscrotum and superior pole of the testes to achieve testicular fixation. If the tunica completely covers the testis and attaches higher up on the spermatic cord (bell clapper deformity), proper testicular fixation does not occur, and there is a predisposition to torsion (Fig. 172-6). In intravaginal torsion, the testicle may rotate within the tunica vaginalis, thereby constricting the arterial blood flow. Extravaginal torsion is seen most commonly in neonates who are premature and also can occur antenatally. If the torsion is prolonged, testicular infarction and atrophy have been reported after as little as 4 hours of ischemia.

Clinical Features. Patients present with acute scrotal pain and swelling, an elevated testicle, and, typically, absence of the cremasteric reflex.31 Although in one series the cremasteric reflex was absent in 100% of patients with torsion and in only 14% of patients with epididymitis, the presence of the cremasteric reflex does not preclude testicular torsion. Abnormal epididymal and testicular position also may be noted, with left-sided torsions slightly more common than right. Nausea, vomiting, and a low-grade fever also may be seen. In the patient with an undescended testicle who presents with abdominal pain, torsion should be a consideration.32

Diagnostic Strategies. Unless an alternative diagnosis is absolutely secure (e.g., epididymitis), the patient should be evaluated for testicular torsion. Alternatively, with a relatively confident clinical diagnosis of torsion, diagnostic testing should not delay appropriate management. Results of a urinalysis are rarely helpful as pyuria can be seen in cases of testicular torsion and epididymitis. The widely preferred diagnostic study for the prospect of torsion is color flow Doppler ultrasonography. This technique has a sensitivity of 79 to 86%, with a specificity of almost 100%, for detection of testicular torsion. In contrast with scintigraphy, it can be performed rapidly, often is available 24 hours a day, and does not require that an intravenous line be placed. Scintigraphy has a sensitivity ranging from 79

to 100% and a specificity of 89 to 100%. Magnetic resonance imaging (MRI) has recently been evaluated as another diagnostic modality, with a sensitivity in one study of 93% and specificity of 100%. In cases of indeterminate ultrasonound findings, the urology consultant should be notified for disposition decisions; in addition, scintigraphy may be performed as resources allow. When clinical suspicion is strong, surgical exploration should not be delayed for diagnostic studies, especially in patients in whom duration of symptoms is less than 12 hours.

**Management.** If the patient presents within 12 hours of symptom onset, immediate surgical exploration is indicated, predicated on clinical findings or confirmatory clinical studies. Detorsion of the affected testicle is performed, followed by an elective orchiopexy of the contralateral side to avoid recurrence. Approximately 40% of patients have a bell clapper deformity of the contralateral testicle. Manual detorsion also may be performed by rotating the testicle in an “open book” fashion as viewed from below, from medial to lateral, until detorsion is complete. Because the procedure is painful, sedation and pain relief should be considered before this intervention. Manual detorsion should be attempted only if there is a delay in getting a urologist to come in for operative detorsion and the patient has had continuous pain for less than 24 hours or if, in the judgment of the emergency physician, the time zone of opportunity to salvage the testis has not passed.

**Torsion of the Testicular Appendage**

The appendix testis is a remnant of the müllerian duct. The appendix testis is involved in 92% of the cases of testicular appendage torsion, and the appendix epididymis is involved in the remaining cases. The average age at occurrence is 10 years. Patients typically present with moderate pain of sudden onset that is localized to the involved hemiscrotum. The pathognomonic “blue dot” sign, a small area with a bluish hue less than 3 mm across located in the upper lateral portion of the hemiscrotum, is present in less than 25% of cases and represents the cyanotic appendage below the scrotal wall. If any doubt exists about the diagnosis, a nuclear radioisotope scan or color Doppler ultrasound study should be performed. Color Doppler ultrasonography reveals normal or increased flow to the affected testicle. Conservative therapy with analgesics usually is all that is indicated, with the involved appendage undergoing autoamputation within 1 week accompanied by resolution of symptoms.

**Varicocele**

A varicocele is a collection of venous varicosities of the spermatic veins in the scrotum caused by incomplete drainage of the pampiniform plexus. Incidence rates of 14 to 16% in adolescent males have been reported, but varicoceles are rare in children younger than 10 years. Left-sided varicoceles account for 85 to 95% of cases; however, bilateral varicoceles may be present in up to 22% of patients. Intra-abdominal pathology should be suspected in cases of right-sided varicocele because these usually are caused by inferior vena cava thrombosis or compression of this vessel by tumors. The acute presentation of a left-sided varicocele should raise suspicion for renal cell carcinoma with obstruction of the left renal vein. The dilated venous collection may be tender on physical examination, can be palpated superior and posterior to the testis, and usually is more pronounced with the patient in the upright position; therefore, the patient should be examined in both the standing and supine positions. Patients in whom scrotal swelling persists in the supine position should be evaluated with a computed tomography (CT) scan of the abdomen, with oral and intravenous contrast administration for conditions obstructing the renal vein. Varicoceles have been described as a “bag of worms” both in appearance and on palpation. Surgical correction may be required if the patient becomes symptomatic or has bilateral varicoceles.

**Idiopathic Scrotal Edema**

Idiopathic scrotal edema is painless erythema and induration of the scrotum, with 77% of cases occurring before the age of 10 years. Two thirds of cases are unilateral, and no specific allergens have been identified. The condition is characterized by the development of painless erythema and induration of the scrotum, which may be pruritic. There is minimal tenderness on physical examination, but the edema and erythema may extend to the phallus, groin, and abdomen. Examination of the testes and epididymis reveals no palpable masses. Systemic signs and symptoms are rare. Patients can be discharged home with outpatient follow-up after an acute pathologic process has been ruled out. Most cases resolve spontaneously within a few days and do not require any specific treatment. Recurrence rates of up to 21% have been described.

**Hydrocele**

A hydrocele is a collection of fluid that accumulates in the tunica vaginalis. Communicating hydroceles result when the upper processus vaginalis fails to obliterate, leaving an open tract between the peritoneum and the scrotum. The tract is closed in noncommunicating hydroceles. Most hydroceles are rightsided. They may be present at birth, but they usually are painless and worsen with crying or exertion. Hydroceles often resolve spontaneously by the age of 18 months. Examination with transillumination reveals enlargement of the scrotum. Color flow Doppler ultrasonography or radionuclide scintigraphy may be necessary to determine the cause of the hydrocele and to exclude an acute pathologic process in patients with acute symptoms of pain; otherwise, asymptomatic patients can be discharged home with urologic follow-up. Patients with a hydrocele that has persisted for more than 1 year or who are older than 18 months should undergo ultrasonography to ensure that the hydrocele is not a reactive hydrocele caused by testicular tumor or inflammation.

**Inguinal Hernia**

**Principles of Disease.** Inguinal (direct and indirect) hernias are more common in males, with bimodal peaks before 1 year of age and then again after the age of 40 years. An indirect inguinal hernia occurs when the processus vaginalis does not obliterate in infancy and abdominal contents invaginate through this patent sac. Entrapment of mesentery, bowel, intraperitoneal organs, and the hernial sac can occur and is more common with small hernias. If the contents of the hernia can be returned to their anatomic position, the hernia is reducible; if the contents remain entrapped, it is incarcerated or irreducible. Hernias that remain incarcerated can undergo strangulation, with resultant necrosis of bowel or mesentery.

**Clinical Features.** Patients with incarcerated hernias may present with pain, edema extending to the scrotum, nausea, vomiting, and low-grade fever. Physical examination may reveal bowel sounds in the scrotal sac. If the inguinal mass can be palpated separately from the testes, it is possible to diagnose an inguinal hernia on clinical grounds alone. Rarely, the incarcerated and strangulated hernia can manifest as a tense blue mass in the scrotum.
Management and Disposition. The patient should be placed in the Trendelenburg position with an ice pack applied to the groin to reduce swelling; sedation may be necessary before reduction. Slow, gentle pressure should be applied to reduce the hernia. If the pressure technique is not successful in reducing the hernia, the opposite technique can be tried: The hernia mass can be “pulled” to straighten out the entrapped contents, thereby allowing them to slip back into the abdomen.

If the hernia cannot be reduced or strangulation is suspected (as indicated by fever, overlying cellulitis, or signs of peritonitis), the patient should receive fluid resuscitation, broad-spectrum parenteral antibiotics, and an emergent surgical consultation.34

Patients who are found to have a hernia on routine examination or who have had the hernia reduced and are without symptoms suggestive of incarceration or strangulation should be referred for surgical repair.

Carcinoma

Principles of Disease. Testicular and scrotal cancer represents approximately 1% of solid tumors in children. An increased incidence of testicular cancer, in both the undescended testicle and the contralateral descended testicle, has been noted in patients with cryptorchidism. Tumor types include teratomas, embryonal carcinomas, yolk sac tumors, choriocarcinomas, Leydig cell tumors, and Sertoli cell tumors. Lymphoma and leukemia can metastasize to the testicle as well.

Patients typically present with a painless unilateral mass palpated separately from the testis or may describe a feeling of fullness, tugging, or increased weight of the scrotum and testicular enlargement. A reactive hydrocele may be present in 7 to 25% of patients and can lead to a delay in diagnosis. Physical examination reveals a firm mass, smooth or nodular, that is not transilluminated. A complete physical examination looking for lymphadenopathy, petechiae, abdominal mass, hepatosplenomegaly, or gynecomastia should be performed.

Diagnostic Strategies. Diagnostic evaluation includes a CBC, urinalysis, urine human chorionic gonadotropin (produced by germ cell tumors) assay, and ultrasonography of the testis.

Management and Disposition. ED management includes prompt referral for urologic and oncologic consultation. Admission to the hospital to facilitate the evaluation may be necessary.

Urinary Tract Infections

Perspective. Sequelae of untreated urinary tract infections may include sepsis and renal scarring, and accurate and early diagnosis is important. At the same time, avoiding unnecessary evaluation and treatment of children at lower risk for these infections is cost-effective and minimizes the chance for iatrogenic harm. Diagnosing urinary tract infections in infants and young children can be challenging because the clinical signs often are nonspecific and obtaining useful urine specimens can be difficult.

Principles of Disease. The risk of developing urinary tract infections before the age of 12 years is approximately 5% for girls and 1% for boys. Neonatal boys are more susceptible to urinary tract infections than girls, but beyond that period, infections in females prevail. Girls younger than 2 years and uncircumcised boys younger than 6 to 12 months also are especially at risk.46

Seven percent of children younger than 2 years with a temperature greater than 39°C and presenting without a source for the fever have an occult urinary tract infection.46,47 Moreover, up to 4% with a significant fever and an associated upper respiratory tract infection or acute otitis media also may have a urinary tract infection.46,48 By comparison, the background prevalence of asymptomatic bacteriuria is estimated to be 1 to 2% in all children.49

On the basis of renal nuclear scans, it is estimated that 75% of children younger than 5 years with a febrile urinary tract infection have pyelonephritis.46 Vesicoureteral reflux from the bladder into the ureter is a common cause of the pyelonephritis and renal scarring. Urinary tract infection in infants younger than 3 months is associated with bacteremia in up to 50% of cases; in children older than 3 months, the risk drops to 5%. Renal scarring can occur in 27 to 64% of children after pyelonephritis and may lead to renal failure and a risk of hypertension later in life.46

E. coli is the predominant cause of urinary tract infections in children, with Klebsiella species more likely to be the etiologic agents in newborn children. Enterobacter, Proteus, Morganella, Serratia, and Salmonella species also are important pathogens.50 In neonates and young infants, bacteremia is considered the route of infection to the urinary tract. In older children, infection in the lower tract often is the source of upper tract infection. A common cause of urinary tract infections in toilet-trained girls is believed to be improper wiping after urination. Young girls should be taught to wipe from anterior to posterior (front to back) after urination.

Clinical Features

Infants and Children Younger than 2 Years. Signs and symptoms usually are nonspecific and include decreased oral intake, lethargy, jaundice, fever, vomiting, abdominal pain, and irritability.

Young children may not be able to verbalize when urination is painful. It is assumed that a urinary tract infection in this age group represents upper tract disease and would therefore arise with more systemic symptoms and signs.

Children Older than 2 Years. Urinary tract infection in children older than 2 years can be either an isolated cystitis or upper tract disease with symptoms and signs of a more systemic nature. Cystitis usually is associated with local symptoms (i.e., suprapubic tenderness and dysuria). Clinical manifestations of pyelonephritis may include fever, costovertebral angle tenderness to palpation, abdominal pain, vomiting, and ill appearance. New-onset bedwetting also may be a sign of a urinary tract infection.

Diagnostic Strategies. Various techniques can be used for collecting urine samples from children. Because of the difficulty in cleaning the perineal area, the bag collection method is associated with an increased risk of contamination by periurethral flora, with false-positive results ranging from 12 to 83%.46 Thus, the bag collection method is not recommended in infants and children who are not toilet-trained. Because urethral catheterization is almost always successful, suprapubic aspiration to obtain a urine sample is rarely needed.49,50 A suprapubic bladder aspiration also is used for young infants because the expanded bladder is located more intrabdominally. Chances of a full bladder and successful aspiration improve if 45 to 60 minutes have elapsed since the last diaper change. The use of ultrasonographic guidance has been advocated to enhance the probability of obtaining urine by the suprapubic and catheterization methods.51,52

Urethral catheterization is relatively simple and poses little risk, although it may be more difficult in uncircumcised boys or in young infants. There is a slight risk of both trauma to the urethra and the introduction of bacteria into the urinary tract with this technique. A 5F feeding tube can be used in young infants. Young male infants sometimes spontaneously urinate when the urethral meatus is cleansed; a midstream clean-catch urine specimen may then be obtained.

For a clean-catch urine sample from a toilet-trained child, the parent can clean the child’s urogenital area with soap and
water before urination. Children can be instructed to sit backward on the toilet to urinate, allowing better access for obtaining the urine specimen. A urine sample with more than 10 white blood cells (WBCs) per high-power field and a large number of epithelial cells must be considered contaminated, and either an improved clean-catch method or catheterization must be tried. Females with a vaginal discharge, regardless of age, should be catheterized.

In children younger than 2 years, a urinalysis alone is not considered adequate for ruling out urinary tract infections. As many as 10 to 50% of patients with urinary tract infection can have false-negative results on urinalysis. If both markers are positive, the false-positive rate is less than 4%. Gram’s stain of the urine has a sensitivity of 93%. Depending on the technique used to obtain the urine culture, criteria for a definitive diagnosis of urinary tract infection vary (Table 172-1).

Renal function tests are rarely abnormal but should be performed in children with hypertension, hematuria, proteinuria, or signs of dehydration. In general, blood cultures are not indicated in a majority of children with urinary tract infection. The true-positive rate for blood culture in the presence of a urinary tract infection is low, and the organism identified is invariably the same as the organism in the urine culture.

Differential Considerations. Underlying renal disease or urinary tract abnormality considered in a child presenting with hypertension, hematuria, or difficulty with urination or should be suspected in children with elevated BUN or creatinine, electrolyte abnormalities, or acidosis on laboratory examination. CT of the abdomen may be necessary to delineate the extent of urinary tract abnormalities.

Several other causes of dysuria in children are recognized (Box 172-1). Irritants such as bubble bath or soaps may cause local irritation and dysuria. A retained foreign body in the vagina (such as toilet paper) can cause irritation or bacterial growth with associated dysuria and vaginal discharge. Pinworms in the genitourinary area can cause itching and scratching. Balanitis in uncircumcised boys also can cause dysuria and pyuria.

Accidental injuries to the genital area can cause abrasions or lacerations and subsequent dysuria. Sexual or physical abuse must be considered in any young child with a history of multiple urinary tract infections.

Management

Infants Younger than 2 Months. Young infants with urinary tract infections are at risk for associated sepsis. The age at which a urinary tract infection warrants hospital admission has decreased dramatically. Today, infants younger than 2 months of age are considered to be at high risk for the development of sepsis and should therefore be admitted to the hospital for intravenous antibiotic therapy (e.g., with gentamicin and ampicillin).

Children 2 Months to 2 Years. Although inpatient treatment of children with suspected pyelonephritis has traditionally been recommended, studies now show that well-appearing children without signs of toxicity may be managed as outpatients. A recent meta-analysis of data from both adult and pediatric studies found no significant evidence suggesting that oral antibiotic therapy is less effective than parenteral or initial parenteral therapy for treatment of severe urinary tract infection. Community antimicrobial resistance patterns are important to consider in deciding on an appropriate antimicrobial. Rates of *E. coli* resistance to trimethoprim-sulfamethoxazole can be as high as 20 to 30% in some communities. The first dose of a parenteral antibiotic and a double dose of an oral antibiotic appear to be equivalent. Because urinary tract infections in this age group are considered to be upper tract disease processes, a longer course of antimicrobials is indicated (e.g., 10 to 14 days). Although a review of studies found no difference in the frequency of positive urine cultures between short-course therapy (2 to 4 days) and longer-course therapy (7 to 14 days), most of these studies mixed children younger than 2 years with older children, including adolescents. Thus, the recommendation for short-course therapy in children younger than 2 years is not supported at this time. Follow-up in 2 to 3 days is essential to evaluate the culture and sensitivity results and to assess clinical status. Additional outpatient follow-up, including appropriate imaging studies, is recommended to determine the presence of renal scarring, posterior urethral valves, or vesicoureteral reflux.

Children Older than 2 Years. In older children with simple cystitis, a short 3-day course of antibiotics, such as trimethoprim-sulfamethoxazole or amoxicillin-clavulanate, is adequate. Shorter courses result in higher failure rates and are not indicated. In older children with pyelonephritis, a longer course of antibiotics (generally 14 days) is recommended. In the adult population, a more recent study shows that a 7-day course of a fluoroquinolone is as effective as a 14-day course of trimethoprim-sulfamethoxazole. In children, fluoroquinolones are still contraindicated because of the presumed effect on cartilage growth.

Disposition. Children with signs of toxicity, urinary obstruction, or inability to take oral medications should be hospitalized for intravenous antibiotic therapy. On discharge, parents
Etiology of Hematuria in Children

**Extrarenal**
- Trauma
- Meatal stenosis or posterior urethral valves
- Exercise
- Menstruation or rectal bleeding
- Foreign bodies
- Cystitis, urethritis, or epididymitis

**Intrarenal**
- Pyelonephritis
- Renal or bladder stones or tumors
- Poststreptococcal or idiopathic glomerulonephritis
- Acute interstitial nephritis
- Acute tubular necrosis
- Baseline membrane glomerular disease
- Renal vein or arterial thrombosis
- Recurrent familial hematuria
- Polycystic kidney disease

**Systemic**
- Henoch-Schönlein purpura
- Systemic lupus erythematosus
- Hemolytic-uremic syndrome
- Infectious mononucleosis
- Sickle cell disease or other hemoglobinopathies
- Bacterial endocarditis or artificial cardiac valves
- Bleeding disorders, warfarin, or aspirin
- Medications such as amitriptyline or chlorpromazine, radiocontrast dyes
- Munchausen syndrome or factitious

---

**Hematuria**

**Perspective.** Hematuria is common in the pediatric population. Hematuria, defined as the presence of red blood cells (RBCs) on examination of two successive urine samples, has a prevalence rate of 1 to 2% in children ages 6 to 15 years of age.67 Microscopic hematuria is defined as the presence of more than 5 RBCs/mm³ and is detected using chemical reagent strips and microscopic urinalysis. Persistent hematuria is defined as positive results on three urinalyses over a 2- to 3-week period.67 Macroscopic or gross hematuria is presence of blood in the urine visible to the naked eye and may be associated with clots.

**Principles of Disease.** Hematuria results from the entry of RBCs into the urinary tract. Inflammation, infection, trauma, or anatomic abnormalities can occur anywhere from the glomerulus to the urethra. The endothelium and basement membrane of the glomerulus usually are impervious to large proteins such as RBCs and hemoglobin, but myoglobin may pass freely. Damage to the glomerulus, however, may allow RBCs and hemoglobin to pass into the collecting system.

Urine with lysed RBCs tests positive for hemoglobin and negative for RBCs and may be pink in color. Urine containing myoglobin from muscle breakdown tests positive for hemoglobin and negative for RBCs. Evaluation of creatine kinase and fractionated bilirubin levels and hematocrit often can help differentiate hemoglobinuria from myoglobinuria. Not all red urine contains blood. Certain drugs or foods such as phenothiazines, ibuprofen, beets, and blueberries can cause reddish-colored urine. In neonates, urate crystals can cause red-tined urine in the diaper. *Serratia marcescens*, a fecal pathogen, can cause a red pigment when left in the diaper. Bleeding from the vagina or rectum can sometimes be mistaken for blood in the urine.

**Clinical Features.** The history and physical examination should focus on signs of infection, trauma, or bleeding disorders. Signs of renal disease (e.g., hypertension), edema, rales, and cardiac murmurs are important findings. An examination of the genitilia may reveal inflammation or bleeding.

**Differential Considerations.** The etiology of hematuria comprises a diverse group of disorders and conditions (Box 172-2). Presence of RBCs in the urine as a result of trauma is discussed elsewhere.

Extrarenal causes of hematuria include urethral valves and meatal stenosis. Extensive exercise can also cause hematuria as a result of both direct renal trauma and ischemic injury.

Intrarenal disorders include pyelonephritis, renal or bladder tumors, poststreptococcal acute glomerulonephritis, and basement membrane disease of the glomerulus.

Systemic illnesses that cause hematuria such as Henoch-Schönlein purpura and hemolytic uremic syndrome (HUS) are discussed later in this chapter. Other systemic causes of hematuria include bleeding disorders, aspirin, and anticoagulants.

**Diagnostic Strategies.** A urinalysis that shows more than 5 RBCs per high-power field indicates hematuria. The presence of WBCs or leukocyte esterase should be noted. Casts in the urine or proteinuria demonstrates a glomerular origin for the hematuria. If glomerular disease is suspected, a throat culture, antibody test for streptococcus, complement studies, erythrocyte sedimentation rate determination, antinuclear antibody assay, or hepatitis B serology tests should be considered. If the patient has signs of hypertension, edema, or proteinuria, laboratory tests for electrolytes, total protein, and albumin should be ordered.68

A 24-hour urine collection for creatinine and protein should be evaluated for asymptomatic hematuria. Urine and plasma calcium levels should also be measured.

Noncontrast helical CT is the current study of choice for the identification of renal stones. It has exceptional sensitivity and specificity for detection of calculi as small as 1 mm and can identify associated processes such as obstruction, hydrourereter, hydrocalyx, and renal abscess. In addition, it is superior to intravenous pyelography in determining alternative diagnoses such as abdominal tumor.

**Management.** Management of the child with hematuria depends on the underlying cause. The management of the child with renal stones and renal tumors is discussed later on.

**Disposition.** The disposition of a child with hematuria depends on the underlying cause. Simple cystitis or pyelonephritis can be treated in the ED with follow-up by the child’s primary care physician. A child diagnosed with a renal tumor or stone should be referred to a nephrologist or urologist. Children with acute renal failure, especially with those with signs of fluid overload or hyperkalemia, need to be hospitalized for appropriate management.

**Renal Stones**

**Perspective.** Renal stones result from a complex process of crystallization involving growth inhibitors and promoters and changes in urine pH and flow. Congenital abnormalities,
trauma, or infection also can be an inciting cause. An increased risk for hypercalciuria and the formation of renal stones often is inherited.

**Principles of Disease.** Renal stones are uncommon in children, with approximately 1 case diagnosed for every 1000 pediatric hospital admissions. Calcium-containing stones are responsible for approximately 60% of all cases, followed by struvite (infection), uric acid, and cystine stones. Renal stones are three to four times more common in white children than in nonwhite children. Family history also seems to play a role in the formation of kidney stones.

**Clinical Features.** The signs and symptoms of renal stones in older children typically include colicky flank pain, vomiting, and hematuria. Younger children with renal stones also can present with less specific complaints, such as nontender abdominal pain, vomiting, or malaise. In a study from the United Kingdom, 17% of pediatric patients with renal stones were found to present with hematuria only, without flank or abdominal pain. In the initial evaluation of children with possible renal stones, the history should ascertain potentially relevant factors including previous urinary tract infections, especially those caused by organisms such as *Proteus* species; family history of renal stones; and diet (including excessive vitamin use) and fluid intake.

Obstruction of the collecting system can sometimes lead to infection, papillary necrosis, or decrease in renal function. Fever in the presence of a renal stone should be taken as an indicator of upper tract infection.

**Diagnostic Strategies.** In children suspected of having renal stones, the urine should be checked for hematuria, leukocytes, and bacteria. The urine also should be strained and any crystals sent for analysis. Other laboratory tests to consider are CBC, electrolyte panel, and determination of BUN, creatinine, uric acid, total protein, and albumin. Ninety percent of renal calculi are visible on a plain abdominal radiograph, although stool can sometimes obscure the view. Other types of calcifications appearing on plain abdominal radiographs include gallstones, phleboliths, vessel or lymph node calcifications, and calcified malignancies. Plain films of the abdomen have no additional value over CT scan of the abdomen and should not be obtained in lieu of the CT scan.

Children with suspected kidney stones should have a non-contrast-enhanced CT scan of the urinary tract, called a CT urogram. A CT urogram may be obtained to define the anatomy and other potential causes of hematuria, such as a tumor or pyelonephritis; a CT urogram also avoids the use of nephrotoxic radiocontrast material. The intravenous pyelogram should be reserved for treatment centers without access to CT. Ultrasoundography may be used in patients with a history of renal stones to follow the progress of a stone or in patients with frequent stones to eliminate the need for repeat CT scans and the attendant radiation exposure.

**Differential Considerations.** The differential diagnosis for colicky flank or abdominal pain in the pediatric patient generates a long list of possibilities. Gastroenteritis and constipation are more common causes of colicky abdominal pain in young children than kidney stones. Intussusception most commonly occurs in children younger than 2 years and can manifest with intermittent abdominal pain. In adolescents, biliary colic and intermittent gonadal torsion also must be considered.

**Management.** Initial pain management should include a narcotic analgesic in conjunction with a longer-acting nonsteroidal anti-inflammatory drug (NSAID). The analgesic effect of NSAIDs is directly related to the inhibition of prostaglandin-mediated contraction of the ureter and is characteristic of all NSAIDS (e.g., ibuprofen, naproxen, ketorolac). Patients with signs of volume depletion or with a history of fever, vomiting, or poor fluid intake should be adequately hydrated to improve urine flow and prevent urinalysis, which may contribute to stone formation. Excessive fluid administration to increase urine flow, to enhance movement of the stone down the urinary tract, however, has not been proved to be effective.

After cultures have been obtained, children with infected urinary tracts with stones should be treated with antibiotics; hospitalization generally will be required. Children with larger renal stones may undergo shockwave lithotripsy as a therapeutic modality. In some centers, ureteroscopy also may be a management option for larger stones.

Children with normal renal function and adequate pain control, without signs of toxicity or renal infection, can be safely discharged home with good follow-up. Follow-up with a nephrologist or urologist may include parathyroid hormone assay, analysis of fasting urine samples for calcium-to-creatinine ratio, or 24-hour urine collection for determination of calcium, magnesium, phosphorus, uric acid, oxalate, cystine, protein, and creatinine.

**Renal Tumors**

**Perspective.** Abdominal masses in children are not uncommon, and in infants the vast majority are benign renal tumors or cysts.

**Principles of Disease.** Renal tumors in children can range from the benign cystic nephroma to the more aggressive malignant rhabdoid tumor. The prognosis will depend on the type and staging of the renal tumor.

**Clinical Features.** The most frequent presentation for a child with a renal tumor is that of an abdominal mass found by the parent while bathing or dressing the child. Hematuria or pain is a less common presenting manifestation than in the adult population.

**Diagnostic Strategies.** Because a significant number of abdominal masses are the result of renal cysts, renal ultrasonography is the imaging study of choice. Ultrasonography can define the mass in question and is not associated with exposure to ionizing radiation. Laboratory tests should include CBC, platelet count, BUN, serum creatinine, urinalysis, and urine catecholamines. Urinary catecholamines are increased in 95% of patients with neuroblastoma but are normal in those with Wilms’ tumor. Any solid masses found on ultrasonography will be better defined by CT of the abdomen. If the mass appears malignant, a CT scan of the chest is indicated to look for pulmonary metastases.

**Differential Considerations.** Considerations in the differential diagnosis for a renal mass include cystic lesions such as those of polycystic kidney disease and severe hydronephrosis resulting from obstruction or severe reflux. Solid masses include Wilms’ tumor, renal cell carcinoma, mesoblastic nephromas, and cystic nephromas.

**Management and Disposition.** Management depends on the function of the urinary tract. Because the renal mass typically involves only one kidney, renal function usually is maintained.

A preliminary diagnosis of the etiology of the mass should be obtained before discharge of the child from the ED. Well-appearing children with normal renal function for whom close follow-up can be ensured may be managed on an outpatient basis. Because of the potential seriousness of a renal tumor, hospital admission should be considered for all children. Consultations with a nephrologist, urologist, and hematologist-oncologist can be coordinated during the admission process.
Proteinuria

**Perspective.** The normal glomerulus is relatively impervious to albumin, a high-molecular-weight protein. Low-molecular-weight proteins, however, pass through the glomeruli and are reabsorbed in the proximal tubule. Proteinuria can result from either increased passage through the glomeruli or decreased reabsorption by the tubules. In most cases, proteinuria is benign and asymptomatic. If the amount of protein lost is significant, such as in nephrotic syndrome, the resultant hypoalbuminemia (albumin less than 2 g/dL and protein less than 4 g/dL) may cause ascites and generalized edema.

**Principles of Disease.** Proteinuria is a common finding in children. Trace to mild proteinuria (1+ to 2+) can be seen in up to 85% of children and adolescents screened, especially during the summer months.75,76

**Clinical Features.** Clinical features seen in a proteinuric child depend on the etiology of the proteinuria. Recent pharyngitis, presence of hematuria, changes in weight or urine output, or family history of proteinuria should be investigated. Abnormal findings may include hypertension, edema, ascites, or palpable kidneys in infants. A butterfly rash of systemic lupus or the presence of hematuria, changes in weight or urine output, or palpable kidneys in infants indicates systemic lupus.

**Differentiation of Disease.** Causes of proteinuria can be divided into glomerular and tubular. Glomerular causes include nephrotic syndrome, glomerulonephritis, and post-transplantation rejection. Transient causes of altered glomerular function include exercise, fever, and seizures. Tubular causes of proteinuria include heavy-metal poisoning, urinary tract infections, and diabetes; an asymptomatic tubular proteinuria also has been described.75,76 False-positive results on urinary dipstick testing for proteinuria can be obtained when the urine is alkaline or when it contains mucus, blood, vaginal secretions, semen, or a significant number of inflammatory cells.

Orthostatic proteinuria is a benign condition characterized by the presence of protein in the urine collected with the patient in an upright position but not in samples collected from a supine child. Proteinuria that is persistent or associated with hematuria or other signs of renal disease usually is a sign of a more serious condition.

**Diagnostic Strategies.** Mild proteinuria (2+ or less; equivalent to 100 mg/dL, or less) requires no further investigation unless there are signs of infection. Moderate proteinuria (3+ or greater; equivalent to 300 mg/dL or greater) necessitates additional evaluation with laboratory tests for serum total protein and albumin, serum electrolytes, BUN and serum creatinine, and urine culture. A 24-hour urine collection for protein also is indicated. The urine protein-to-creatinine ratio (urine Pr/Cr, expressed in mg/dL) in a random urine sample, however, correlates strongly with the protein levels found in a 24-hour urine collection.75 Urine Pr/Cr less than 0.2 mg/dL is considered normal for children older than 2 years and for adults. Children 6 months to 2 years of age normally have a ratio of less than 0.5 mg/dL. A urine Pr/Cr greater than 3.0 mg/dL is consistent with nephrotic syndrome.

Antistreptolysin O (ASO) titer can be measured to identify a previous streptococcal infection as the cause of the proteinuria. In young children, renal ultrasonography detects polycystic disease or anatomic abnormalities. Referral to the child’s primary care physician or a pediatric nephrologist for follow-up and renal biopsy is indicated. Renal biopsy may be indicated in patients with increased creatinine levels, low complement levels, or hematuria.77

**Management.** The approach to management for a child found to have proteinuria depends on the underlying cause. Management of children with poststreptococcal glomerulonephritis and nephrotic syndrome is discussed later in the relevant sections for these topics.

**Disposition.** A child with significant edema and ascites from the loss of albumin needs to be hospitalized. Children with significant hypertension resulting from glomerulonephritis or with marked impairment of renal function also need to be hospitalized. Well-appearing children for whom good follow-up can be ensured can be discharged home.

Poststreptococcal Glomerulonephritis

**Perspective.** Poststreptococcal glomerulonephritis (PSGN) is one of the sequelae of streptococcal pharyngitis and, less commonly, infections of the skin. Treatment of streptococcal pharyngitis with antibiotics has not been shown definitively to decrease the incidence of PSGN, as opposed to acute rheumatic fever, another sequela of streptococcal pharyngitis.

**Principles of Disease.** PSGN is not well understood but probably results from deposition of circulating immune complexes in the kidney.78 This results in decreased glomerular filtration, allowing proteins to flow freely into the urine.

**Clinical Features.** PSGN most commonly occurs in children 3 to 7 years of age, usually with a history of pharyngitis with fever 2 weeks before the onset of glomerulonephritis. Symptoms either can be localized to the urinary tract, manifesting as hematuria or flank pain, or may be less specific, such as lethargy or generalized edema. Some children may present with more significant clinical signs such as pulmonary edema, cardiac arrhythmias, or significant hypertension. Renal failure is found in 2% of these patients.79,80

**Diagnostic Strategies.** Urinalysis shows significant blood and protein, with RBC casts in 60% of cases. Pyuria with granular or hyaline casts also may be found.

The ASO and immunoglobulin G levels are elevated in PSGN. Total complement levels, especially C3, are decreased in most patients during the first 2 weeks of the illness. The complement levels should return to normal within 3 to 4 weeks. The BUN is elevated; hyponatremia and hyperkalemia also may be present.80

**Differential Considerations.** Considerations in the differential diagnosis include the entities previously mentioned regarding proteinuria, including nephrotic syndrome and urinary tract infection.

**Management and Disposition.** Management includes restricting fluid and salt intake and sometimes using diuretics. A child with significant hypertension, congestive heart failure, or uremia requires hospitalization for inpatient management. Significant hypertension should be treated as outlined in the section on hypertension.

Children with mild symptoms in whom good follow-up can be ensured can be managed on an outpatient basis.

Nephrotic Syndrome

**Perspective.** Nephrotic syndrome is characterized by hypoproteinemia, proteinuria, and edema. Primary nephrotic syndrome applies to diseases limited to the kidney; renal biopsy is used to stratify patients and determine therapeutic and prognostic decisions. Secondary nephrotic syndrome results from systemic illnesses such as PSGN.

**Principles of Disease.** From 2 to 7 cases of nephrotic syndrome per 100,000 children are discovered each year.77 Boys are affected twice as often as girls, but the distribution equalizes by adulthood. Primary nephrotic syndrome occurs more commonly in children younger than 5 years and secondary nephrotic syndrome more often in older children. Ninety percent of affected children have the primary disease,
with 85% having minimal change nephrotic syndrome, 10% focal sclerosis, and 5% mesangial proliferation (referring to the thin membrane-supporting capillaries surrounding the tubule of nephrons).

The etiology of primary nephrotic syndrome is thought to be idiopathic, but various theories involving bacterial or viral infections, allergic reactions (pollens, poison ivy), or drug ingestions (heroin, mercury) have been investigated. Clinical Features. Characteristics of nephrotic syndrome include edema, hypoalbuminemia, proteinuria, and hyperlipidemia. The onset of edema may be insidious, beginning with periorbital edema. As weight increases, pants and shoes may not fit. The edema progresses, but the child usually does not appear ill unless pulmonary edema or ascites is present. Other features may include anorexia, nausea, and vomiting secondary to edema of the intestine. Hypertension, hematuria, or oliguria may be present. Acute renal failure is rare in primary nephrotic syndrome.

Nephrotic children also are at risk for thrombosis, with a reported rate of thromboembolic complications of 2%. Renal veins are particularly vulnerable to thrombosis, as characterized by flank pain, hematuria, and worsening renal function. Nephrotic children should not undergo punctures to deep vessels because of this risk of thrombosis.

Children with nephrotic syndrome taking corticosteroids also are at risk for side effects of corticosteroid use. Acute mood changes, from depression to mania, are associated with use of steroids. Irritability, excessive crying, and sleeping difficulties can result.

Because of steroid therapy and decreased levels of immunoglobulins, nephrotic children are at risk for bacterial infections, such as from E. coli and Streptococcus pneumoniae.

Diagnostic Strategies. Proteinuria in nephrotic syndrome is defined as excretion of greater than 3.5 g of protein per 1.73 m² per 24 hours or greater than 50 mg/kg per 24 hours. This corresponds to 3+ or 4+ on the dipstick reading. Specific gravity may be high because of the proteinuria. Microscopic hematuria also may be present. Total serum protein usually is low at 4.5 to 5.5 g/dL, and serum albumin is less than 2 g/dL.

Hyperlipidemia may occur because of increased serum cholesterol. Hyponatremia may be present, but other electrolytes usually are normal. If an elevated cholesterol level is present, the lowered sodium level may be a combination of true and pseudo-hyponatremia. BUN and creatinine usually also are normal, and hemoglobin and hematocrit levels may be elevated because of hemoconcentration.

Chest radiographs sometimes show pleural effusions or pulmonary edema. The heart appears normal or small because of hypovolemia. An abdominal radiograph may reveal ascites, and ultrasonography may show a renal abnormality.

Renal biopsy is important for diagnostic and therapeutic decisions and should be performed in older children or in patients with evidence of hematuria, elevated BUN, or persistent hypertension or in whom the renal dysfunction fails to respond to steroids.

Differential Considerations. Other renal diseases that cause edema include glomerulonephritis and renal failure. A vasculitis or acute thrombosis of the renal vessels also must be considered. Gastrointestinal disorders that produce hypoproteinemia include cirrhosis, cystic fibrosis, and protein-losing enteritides.

Management. Despite the edema, children with signs of hypovolemia or shock need to be resuscitated with crystalloid. Hypertension may result from the intrinsic disease; prompt recognition and treatment of this condition are important.

After consultation with a pediatric nephrologist, patients between 12 months and 5 years of age with no gross hematuria and no large loss of protein or complement can be treated with corticosteroids. After the initial evaluation is completed, including a tuberculin test, prednisone at 2 mg/kg per 24 hours PO, divided, two or three times a day can be initiated. Relapses or steroid resistance may necessitate a second course of steroids.

Diuretics such as furosemide, 1 to 2 mg/kg per 24 hours PO or IV in divided doses, may be necessary if respiratory distress or significant ascites is present. Salt restriction may be required. Fluid intake should be restricted only if edema is present despite salt restriction or if the child exhibits hyponatremia because of an impaired ability to excrete excess water.

The relatively immunocompromised status of nephrotic children increases the risk of infection. A fever or signs of peritonitis must be investigated thoroughly. A paracentesis should be performed and fluid sent for cell and differential counts, Gram’s stain, and culture. Hospital admission and antibiotic therapy with agents with activity against S. pneumoniae and E. coli are appropriate.

Disposition. Newly diagnosed patients should be hospitalized for initial evaluation, treatment, and education of both the child and the parents. Patients with signs of shock or respiratory distress should be admitted to the hospital after initial stabilization. Other patients with suspected bacterial infections, peritonitis, edema refractory to therapy, or evidence of renal insufficiency also should be hospitalized.

Acute Renal Failure

Perspective. Acute renal failure results from impaired glomerular filtration rate. Blood pressure, acid-base balance, removal of nitrogen waste, and fluid management all may be affected. The incidence of acute renal failure is unknown, but large children’s hospitals may see 30 to 50 new cases each year.

Principles of Disease. Acute renal failure can be divided into three categories: prerenal, which involves decreased renal perfusion; renal (intrarenal), which is caused by parenchymal damage; and postrenal, which involves obstruction of the urinary tract (Box 172-3).

Causes of prerenal failure include hypovolemia resulting from a variety of factors (e.g., dehydration, burns, hemorrhage), shock (e.g., sepsis, anaphylaxis), and congestive heart failure (e.g., decreased cardiac output). Obstruction of the renal artery or thrombosis of the renal vein also can cause acute renal failure.

Intrarenal causes involve damage to the nephron. Glomerular damage most commonly results from PSGN. Systemic lupus erythematosus, HUS, and sepsis with hyperperfusion are systemic causes of renal failure. Tubular damage can result from heavy metal poisonings or hemoglobin-myoglobin in the tubules from a crush injury, burn, or hemolytic crisis. Cases of acute renal failure in dehydrated children after NSAID use have been reported.

Postrenal failure resulting from an obstruction in the urinary tract may be caused by infection, tumor, renal stones, or posterior urethral valves. Bilateral obstruction of the kidneys usually is necessary for renal failure to occur.

Clinical Features. A child with acute renal failure accumulates nitrogen wastes shown by an increase in BUN and serum creatinine levels. A decrease in urine output is sometimes seen. A urinary output of 1 mL/kg per hour usually is considered adequate, but the output may be lower if the patient is dehydrated. Nephrotoxic agents such as certain aminoglycosides can actually increase the urinary output because of renal tubular damage, but BUN and serum creatinine levels are still elevated.
Acute renal failure can result in life-threatening complications that must be recognized and treated promptly. These include severe hyperkalemia, pulmonary edema or fluid overload, hypertensive encephalopathy, septic shock from renal obstruction and infection, and seizures from metabolic abnormalities or encephalopathy.83

**Diagnostic Strategies.** Preliminary laboratory tests should include CBC; determination of electrolytes, calcium, phosphorus, BUN, and serum creatinine; and a urinalysis with microscopy and culture. Diagnostic studies such as ASO titer (for acute PSGN), C3 complement (for lupus), total serum albumin, cholesterol, and albumin-to-globulin ratio (for nephrotic syndrome and cirrhosis) may be obtained. RBC casts in the urine indicate glomerulonephritis. WBC casts indicate infection as an etiologic disorder, whereas hyaline casts suggest dehydration or acute tubular necrosis.86

Ultrasoundography is the imaging modality of choice for the preliminary evaluation of obstructive causes of renal failure. A noncontrast CT urogram also can readily identify the site of obstruction and avoids the use of nephrotoxic radiocontrast material. A voiding cystourethrogram shows extrinsic pressure on the bladder by posterior urethral valves.

**Differential Considerations.** Significant dehydration can result in temporary decreased urine output and a slight rise in BUN and serum creatinine. After hydration and repletion of intravascular volume, urine output should improve and the elevated BUN and creatinine should resolve. Processes that can result in retention of fluids with associated renal failure include liver disease and decreased cardiac output.

**Management.** The initial management of a child with acute renal failure depends on the clinical evaluation. If hypovolemia resulting from dehydration or blood loss is thought to be the cause of the renal failure, immediate rehydration is necessary. A 20-mL/kg bolus of crystalloid should be given to prevent possible progression to acute tubular necrosis. If no urinary response is obtained after two boluses of crystalloid, diuretics may be useful in the euvolemic patient. Furosemide 1 mg/kg per dose every 2 to 6 hours IV may be tried if there is no evidence of obstruction. Bumetanide, 0.015 to 0.1 mg/kg per dose every 6 to 24 hours IV (maximum of 10 mg per 24 hours), can be useful if furosemide has no effect. Mannitol, 0.75 g/kg per dose every 6 hours IV, also may be helpful but is contraindicated if there is evidence of obstruction.

If the child is considered euvolemic and has no urine output despite diuretic therapy, renal-dose dopamine should be initiated (2 to 5 µg/kg per minute). Consultation with a nephrologist is necessary.84

If hypertension with encephalopathy develops, a controlled 10 to 20% reduction in blood pressure should be achieved using nitroprusside or other intravenous blood pressure agents. Oral medications such as nifedipine or captopril are useful but are associated with the risk of a precipitous drop in blood pressure. Overaggressive reduction in blood pressure can result in hypoperfusion of central target organs such as the brain, heart, and kidneys that have become accustomed to higher perfusion pressures. Further discussion of hypertensive emergencies and treatment can be found in Chapter 83.

Hyperkalemia can result in cardiac dysrhythmias. Potassium levels higher than 6.5 mEq/L may cause changes on the electrocardiogram (ECG) such as peaked T waves and, if significant, widened QRS complexes. Hyperkalemia with resultant ECG changes such as loss of the p wave or widened QRS complex should be treated with calcium chloride 20 to 30 mg/kg per dose (0.2 to 0.3 mL/kg per dose) given IV over 10 to 15 minutes (maximum of 500 mg or 5 mL per dose). Calcium alters the cardiac cells’ action potentials, thereby decreasing the risk of arrhythmias. The calcium dose may be repeated in 5 minutes.

Sodium bicarbonate, 1 to 2 mEq/kg per dose IV every 4 hours, also can be administered. The resultant alkalosis helps move the potassium intracellularly by exchanging H+ for K+. Continued therapy with sodium bicarbonate should be administered in conjunction with pediatric nephrology services because of the risk of increasing volume load with repetitive dosages of sodium. Potassium-binding agents such as sodium polystyrene sulfonate (Kayexalate) are administered orally or rectally and exchange Na+ for K+ in a 1:1 ratio.

Glucose (50% dextrose in water), 0.5 to 1 g/kg, should be given along with regular insulin (1 unit for every 4 g of glucose administered). The insulin temporarily shifts the potassium intracellularly.

Nebulized albuterol also can be used to shift potassium temporarily into the cells and lower serum potassium by 1 to 1.5 mEq/L over 30 minutes.87 Severe cases and those associated with renal failure should be immediately referred to a pediatric nephrologist for emergent dialysis.85

Acute renal failure may lead to seizures caused by either hypertensive encephalopathy or a metabolic derangement—most commonly hyponatremia resulting from dilution of the sodium by free water. Intractable hyponatremic seizures may rarely necessitate the use of hypertonic saline (3% sodium chloride). Each mL/kg of 3% sodium chloride increases the serum sodium by approximately 1 mEq/L. A child with hyponatremic symptoms such as seizures will often improve after receiving 3 to 5 mL/kg of 3% sodium chloride.
Normal saline (0.9%) is relatively hypertonic compared with serum and therefore also may be helpful in correcting the hyponatremia. Water restriction along with the administration of saline usually is only a temporary treatment, because many of these hyponatremic patients ultimately require dialysis.

Sodium bicarbonate will correct a persistent metabolic acidosis and maintain pH 7.1 or greater and a serum bicarbonate level of 15 mEq/L. The base deficit can determine the amount of bicarbonate needed:

$$
\text{Base deficit} = \left[ 0.6 \times (\text{body weight in kg}) \times (\text{desired bicarbonate level} - \text{observed level}) \right] + 2
$$

One-half the replacement is given in the first 3 hours, with the remainder given over the next 24 hours.

Hemodialysis or peritoneal dialysis may be indicated for refractory fluid overload associated with hypertension, congestive heart failure, pulmonary edema, severe hyperkalemia, hyporeninemia, metabolic acidosis, myoglobinuria resulting from burn or crush injuries, or HUS with hemoglobinuria or encephalopathy.

**Disposition.** All children with acute renal failure should be admitted to the hospital. Any child with signs of congestive heart failure, pulmonary edema, significant hyperkalemia, or acidosis should be admitted to a monitored bed.

### Hypertension

**Perspective.** Hypertension is defined as a systolic or diastolic blood pressure higher than two standard deviations above the mean for the age and sex of the patient (Table 172-2). This diagnosis requires three or more accurately measured blood pressures over the course of several weeks. A correct cuff size should be chosen (i.e., the air bladder should cover 80 to 100% of the circumference and two thirds of the length of the upper arm). It is recommended that all children receive yearly blood pressure measurements starting at the age of 3 years. A child who is in pain or agitated may have falsely elevated blood pressure readings.

**Principles of Disease.** Hypertension occurs throughout childhood in both boys and girls. It probably occurs more often in black children than in white children, just as in the adult population. Predisposing factors include obesity, physical inactivity, and a strong family history. Metabolic syndrome, a combination of insulin resistance, hypertension, and hyperlipidemia, may affect up to 50% of overweight adolescents.

Just as in adulthood, primary or essential hypertension is unrelated to a second systemic disease. Children diagnosed with primary hypertension are more likely to become adults with hypertension. Secondary hypertension results from endocrinologic, cardiac, neurologic, or other factors such as exposure to certain drugs or poisons (Box 172-4). In children with significant hypertension, the underlying cause usually is renal (as in glomerulonephritis) or renovascular.

**Clinical Features.** There are a variety of clinical presentations of hypertension in children. First, asymptomatic or mildly symptomatic hypertension may show up in routine vital signs measured in children evaluated in the ED for unrelated illnesses. When asked, these children may complain of headaches, abdominal pain, irritability, or nosebleeds. Sometimes personality changes and difficulties in school are noted.

Urgent hypertension results in severe elevations in systolic or diastolic blood pressures (younger than 10 years of age: systolic blood pressure 160 mm Hg or higher, diastolic blood pressure 105 mm Hg or higher; older than 10 years of age: systolic blood pressure 170 mm Hg or higher, diastolic blood pressure 110 mm Hg or higher) but without signs of end-organ damage.

In children experiencing a hypertensive emergency, clinical signs of end-organ damage will be present. A severe elevation in blood pressure is associated with acute neurologic changes or encephalopathy, pulmonary edema, myocardial ischemia, or proteinuria. The ECG may show signs of ischemia or ventricular hypertrophy. Chest radiography may reveal cardiomegaly or pulmonary edema. Hypertensive emergencies require prompt recognition and treatment. However, overaggressive treatment of long-standing hypertension can produce relative hypotension, leading to worsening neurologic deficit.

Hypertensive encephalopathy symptoms include headache, vomiting, altered mental status, visual disturbances (including blurry vision and diplopia), and seizures or stroke. Papilledema, decreased retinal venous pulsations, and cranial nerve palsies may be found on examination. The diagnosis is confirmed when the symptoms and signs subside rapidly after the blood pressure is lowered. Headache alone, without any other associated symptoms or signs, generally is not considered to represent a hypertensive emergency.

**Diagnostic Strategies.** In addition to a thorough history and physical examination, laboratory and radiologic studies performed in the ED often can determine both the cause of the hypertension and whether a hypertensive emergency exists (Box 172-5).

**Differential Considerations.** Any situation that causes undue agitation or pain in a child can cause a transient rise in blood pressure. Therefore, the diagnosis of hypertension in a pediatric patient should be based only on carefully measured blood pressures in a nonagitated child over several weeks. Secondary hypertension is more likely in symptomatic younger children, especially those without a strong family history.

Other disorders with presentations similar to that of hypertensive encephalopathy include menigitis, brain tumor, intracerebral hemorrhage, stroke, and uremia. These conditions, however, generally produce only a mild increase in the systolic blood pressure; CT or lumbar puncture also can help identify these other diagnoses.

**Management.** The management of hypertensive emergencies also is discussed in Chapter 83. When a child with severe hypertension is seen in the ED, questions should focus on a history of hypertension, urinary tract infections, hematuria, edema, or umbilical artery catheterization. A history of joint pain or swelling, palpitations, weight loss, flushing of the skin, or drug ingestion or a family history is important to ascertain.

A physical examination emphasizing the central nervous system and cardiopulmonary system is indicated. Examination of the fundus may reveal papilledema or hemorrhages. Signs of congestive heart failure or a difference in the upper and lower extremity blood pressures should be noted. A renal

cause of the hypertension may be revealed by the presence of peripheral edema or palpable kidneys. An abdominal or flank bruit suggests renovascular hypertension. Initial laboratory tests should include a CBC, electrolytes, BUN, creatinine, urinalysis, urine culture, chest radiograph, and ECG.

A child in whom clinical findings are consistent with a hypertensive emergency (e.g., acute end-organ damage as found by physical examination, laboratory, or radiologic results) should have intravenous access and be monitored with continuous blood pressure readings; an arterial catheter is preferable. The goal of therapy is to reduce the mean arterial blood pressure by 10 to 20% over several minutes to hours, depending on the nature of the emergency. Headache and vomiting require blood pressure control over several hours, whereas intracranial bleeding or herniation requires reduction over several minutes. Beta-blockers are contraindicated in patients with decreased cardiac output and clinical signs of congestive heart failure. Oral nifedipine is contraindicated in patients with signs of end-organ damage, such as intracerebral bleeding, because of the inability to control the amount of blood pressure reduction. To avoid overaggressive treatment and resultant relative hypotension, medications that can be controlled by intravenous infusions are preferred (Table 172-3).

A hypertensive urgency is severe hypertension without evidence of end-organ damage. These patients should be started or restarted on antihypertensives to prevent end-organ sequelae. Angiotensin-converting enzyme inhibitors or calcium
channel blockers are useful as first-line agents and usually are well tolerated. The child may be observed for a few hours after administration of the medication to evaluate effectiveness or complications. With no evidence of acute end-organ damage, the child can be safely discharged home, assuming that good follow-up can be ensured.

Children with mildly elevated blood pressures (5 to 10 mm Hg above normal) unrelated to the ED visit require repeated blood pressure measurements before treatment for hypertension is begun. If the blood pressure is moderately elevated and the patient is asymptomatic, appropriate management consists of discharge home for outpatient workup of the hypertension and follow-up with the patient's primary care physician for monitoring of blood pressure values. Thiazide diuretics or beta-blockers may be started at low doses.

Disposition. A child with evidence of a hypertensive emergency (i.e., acute end-organ damage) must be hospitalized for evaluation and care in a monitored bed. A child with significantly elevated blood pressure, but without evidence of end-organ damage, can be discharged home if good follow-up can be ensured.

Henoch-Schönlein Purpura

Perspective. Henoch-Schönlein purpura is an immunoglobulin A-mediated systemic vasculitis involving the small blood vessels supplying the skin, gastrointestinal tract, and joints.89 The peak incidence is between 4 and 7 years of age, with an overall occurrence rate of 13.5 episodes per 100,000 children annually.

Principles of Disease. Immune complex deposition results in a systemic vasculitis, with up to 33% of patients experiencing recurrences.89 Approximately 50% of affected children have a history of previous upper respiratory tract infection, and as many as 75% have group A beta-hemolytic streptococci cultured from the oropharynx. Other theorized predisposing factors include exposure to cold weather, certain foods, drugs, and insect bites. Varicella-zoster virus, Mycoplasma species, parvovirus, Campylobacter enteritidis, parvovirus B19, and Epstein-Barr virus also have been implicated.

Clinical Features. The hallmark of Henoch-Schönlein purpura is a palpable, purpuric, or petechial rash most prominent on the lower extremities, starting at the lateral malleoli and extending to the buttocks. The cutaneous manifestations are the initial presenting complaint in 50% of patients. Arthritis or arthralgia occurs in 65 to 85% of patients89 and usually involves the knee and ankle joints. Gastrointestinal manifestations are present in up to 65% of patients, with the most common symptom being dull periumbilical pain resulting from bleeding into the intestinal wall. The abdominal pain typically occurs concurrent with or immediately after onset of the rash; however, in up to 15% of patients, abdominal pain can be the initial complaint.91 A self-limited glomerulonephritis manifested by hematuria develops in 25 to 50% of children. This condition progresses to chronic renal insufficiency in less than 1% of these patients. Children presenting with acute renal failure, nephritic syndrome, or hypertension are more likely to have unfavorable outcomes such as chronic renal failure.92 Testicular involvement occurs in up to 35% of patients; they may present with severe scrotal edema that resembles acute testicular torsion.

Diagnostic Strategies. There are no specific tests to confirm the diagnosis of Henoch-Schönlein purpura, and recognition of the disorder can be difficult if the classic rash is absent at the time of presentation. Screening tests such as urinalysis, BUN and serum creatinine determinations, CBC, and coagulation studies may be needed to rule out other pathologic conditions. Ultrason sound findings in patients with abdominal pain typically include evidence of intraluminal hematomas and duodenal wall thickening.92 Intussusception also may complicate the disease.
Differential Considerations. Considerations in the differential diagnosis include meningococcemia, Rocky Mountain spotted fever, intussusception, trauma, appendicitis, thrombotic thrombocytopenic purpura, juvenile rheumatoid arthritis, bacterial endocarditis, systemic lupus erythematosus, kidney stones, and primary renal disease.

Management. Treatment of Henoch-Schönlein purpura remains controversial because most cases resolve spontaneously and do not require therapy. NSAIDs can be used to treat joint pain, but close attention must be paid to renal function. Corticosteroids have been used to treat severe renal or gastrointestinal involvement. A recent meta-analysis of data on the use of steroids for Henoch-Schönlein purpura found these agents to be effective in reducing the time to resolution of abdominal pain and reduced the odds of developing persistent renal disease. Prednisone or methylprednisolone pulse therapy has shown some benefit, but an acute surgical process must be excluded before initiation of steroids. Therapy for patients with severe renal involvement also includes intravenous immunoglobulins, although promising results also have been seen in patients with severe abdominal pain. Other treatment options for patients with severe Henoch-Schönlein purpura–related nephropathy include early treatment with oral immunosuppressants and possibly the use of methylprednisolone and urokinase pulse therapy. A nephrologist should be consulted for appropriate management of patients with renal involvement, and good follow-up must be ensured.

Disposition. Patients with only the skin manifestations of Henoch-Schönlein purpura usually can be discharged home with symptomatic therapy for the joint pain and malaise. An NSAID or acetaminophen usually is sufficient, but close follow-up should be ensured. Patients with abdominal pain or renal involvement should be admitted for further evaluation and treatment.

Hemolytic-Uremic Syndrome

Perspective. HUS continues to be one of the most common causes of acute renal failure in children. It most commonly affects infants and children, with a mean age at presentation of 3 years, but is rare after 5 years of age. There is no sex predilection, and outbreaks can be sporadic or epidemic, especially when the disorder is related to the most common offending agent, verotoxin produced by E. coli serotype O157:H7. Transmission is through person-to-person contact and also exposure to contaminated food, such as unpasteurized dairy products or beef. Other causes of HUS include Shigella organisms, S. pneumoniae, Aeromonas, human immunodeficiency virus, and drugs; hereditary, familial, and idiopathic forms are recognized as well.

Principles of Disease. Renal compromise is the result of injury to the renal vascular endothelium induced by viral or bacterial agents or the toxins released. Microangiopathic hemolytic anemia then results from injury to the RBCs by fibrin strands along the narrowed blood vessels. Platelets, complement, and fibrin also are deposited in the glomerular lumen, leading to a decrease in glomerular filtration rate and renal failure.

Clinical Features. Patients with HUS present with watery diarrhea, crampy abdominal pain, and occasionally fever. From 2 to 3 days after onset of symptoms, patients experience increased abdominal pain with bloody stools, the latter developing in up to 89% of patients by day 5. Other pathologic features may include toxic megacolon, ischemic colitis, intussusception, perforation, or delayed colonic stricture. After the prodromal gastroenteritis, patients experience sudden onset of hemolytic anemia, thrombocytopenia, and acute renal insufficiency, with possible progression to renal failure. In a meta-analysis published in 2003, death or end-stage renal disease occurred in 12% of cases of diarrhea-associated HUS, and 25% of survivors demonstrated long-term renal sequelae. Pancreatic insufficiency resulting in insulin-dependent diabetes mellitus also has been reported. There are reports of HUS occurring in association with urinary tract infection as well.

Central nervous system irritability may develop and may result in seizures in 40% of patients. Hypertension occurs in up to 50% of patients and may contribute to the development of encephalopathy. HUS recurrences have been associated with a 30% mortality rate.

Diagnostic Strategies. Leukocyte counts and C-reactive protein levels were found to be significantly higher in patients with toxin-producing E. coli O157:H7. The peripheral blood smear shows microangiopathic changes such as teardrop cells, helmet cells, microspherocytes, and burr cells. WBC counts may be elevated, and the platelet count may be less than 50,000/µL. The hemoglobin can be as low as 5 g/dL as a result of the rapid hemolysis that occurs.

Differential Considerations. Considerations in the differential diagnosis of HUS include thrombocytopenic thrombotic purpura, ulcerative colitis, intussusception, and other causes of acquired hemolytic anemia.

Management. Supportive therapy and early peritoneal dialysis account for the reduction in current mortality rates to less than 5%. Patients should be rehydrated; however, it is important not to overload these children with fluids. Hyperkalemia is common and should be treated with sodium bicarbonate, calcium gluconate or chloride, dextrose and insulin, and sodium polystyrene sulfonate (Kayexalate). Patients with severe hyperkalemia, hyperphosphatemia, or severe metabolic acidosis require dialysis.

Packed RBCs (5 mL/kg over 4 hours) typically are administered if the hemoglobin falls below 6 g/dL. Platelet transfusions are required only for life-threatening bleeding or before an invasive procedure. Hypertension is responsive to calcium channel blockers, labetalol, captopril, or nitroprusside in refractory cases. Seizures typically respond to benzodiazepines and phenytoin; however, if they are secondary to hyponatremia, treatment with 3% saline (4 mL/kg) may be indicated. Treatment for the colitis itself also is supportive only, because antimotility agents may lead to toxic megacolon. To date, no randomized trials have been conducted to show the effectiveness of antibiotics for the prevention of the development of HUS. Accordingly, because antibiotics may enhance the release of verotoxin from the bacteria, antibiotics should be avoided. Hyperglycemia, ketonemia, and acidosis secondary to pancreatic islet cell necrosis are managed with insulin therapy.

Idiopathic HUS may be treated with plasmapheresis, especially if neurologic involvement is present. If this therapeutic measure is unsuccessful, renal transplantation may be required. Unfortunately, idiopathic HUS also can recur in the transplanted kidney.

Disposition. Patients with HUS require hospital admission, and consultation with a pediatric nephrologist and a urologist should be arranged. Early dialysis and supportive therapy result in return to baseline renal function in up to 90% of patients with acute renal failure.
KEY CONCEPTS

- **Priapism**: In low-flow priapism, cavernosal aspiration plus irrigation has been effective when performed within the first 48 hours, and preferably within a few hours, of symptom onset. Phentolamine, phenylephrine, ephedrine, or 1:1,000,000 epinephrine often is added to the irrigation solution used in performing corporal aspiration.

- **Phimosis and paraphimosis**: Use of steroid cream is first-line therapy for phimosis. In paraphimosis involving vascular compromise of the glans penis, a dorsal split procedure may be necessary.

- **Testicular torsion**: Delay in diagnosis and treatment can result in loss of spermatogenesis and, in severe cases, a necrotic, gangrenous testis. Testicular salvage rates are time dependent, with a 96% success rate if detorsion is performed less than 4 hours after symptom onset; with greater than a 24-hour delay in time to treatment, the success rate decreases to less than 10%.

- **Varicoceles**: Left-sided varicoceles account for 85 to 95% of the cases; intra-abdominal pathology should be suspected in cases of right-sided varicoceles because these usually are caused by inferior vena cava thrombosis or compression of this vessel by tumors.

- **Urinary tract infections**: In children younger than 2 years, a urinalysis alone is inadequate for ruling out urinary tract infections because this study yields false-negative results in as many as 10 to 50% of patients.

Many acute neurologic manifestations of disease that precipitate a visit to the emergency department (ED), such as seizure, vertigo, ataxia, or headache, appear in both adults and children. However, associated signs and symptoms and diagnostic considerations in children are quite different from those in the adult population. Moreover, bacterial meningitis, once a predominantly pediatric disease, is now mainly a disease of adults; yet it remains imperative to recognize subtle signs and symptoms of this lethal disease in infants and young children.

ACUTE BACTERIAL MENINGITIS

Perspective

Despite advances in medical care, acute bacterial meningitis (ABM) remains a potentially life-threatening emergency. Nationwide mortality rates for treated cases are 20 to 30% in neonates and adults and 2% in infants and children.1 With the recommendation in 1991 that all infants, starting at 2 months of age, receive the conjugated vaccine against Haemophilus influenzae type b, the incidence of bacterial meningitis caused by this organism has been reduced in children by more than 99%.1,2 Even with the best care, however, 10 to 30% of survivors of meningitis of all types demonstrate persistent, functionally important disabilities.3,4 These include hearing deficits, seizures, learning and behavioral problems, and cognitive impairments.

Infants and Children

Beyond the neonatal period, in the United States, S. pneumoniae and N. meningitidis account for 90% of the documented cases of ABM. Unusual pathogens include Salmonella species, Campylobacter species, L. monocytogenes, group G streptococci, Francisella tularensis, group B beta-hemolytic streptococci, and several anaerobic organisms.1,2 Recent advances involving the heptavalent pneumococcal conjugate vaccine (PCV7), which has been recommended for all children younger than 2 years of age, have dramatically reduced the number of cases of bacterial meningitis caused by invasive pneumococcal disease.7

Principles of Disease

Host factors influence the degree of susceptibility to meningitis. Newborn infants younger than 1 month of age, particularly those born prematurely, are at greatest risk for ABM owing to their immunologic immaturity. Other groups predisposed to ABM include males, Native Americans, African Americans, malnourished persons, indigent urban dwellers, daycare center attendants, and patients with compromised immune status from sickle hemoglobinopathies, acquired immunodeficiency syndrome (AIDS), asplenia, renal disease, hepatic disease, diabetes mellitus, or dysgammaglobulinemia, as well as those undergoing immunosuppressive treatment, including corticosteroid therapy.

Bacterial meningitis is thought to develop through the interconnection of (1) infection of the respiratory tract, (2) development of bacteremia, (3) invasion of the meninges, and (4) inflammation of the meninges and brain.6 Invasion of the meninges by bacterial pathogens is facilitated by mechanical disturbances. These include recent neurosurgical procedures such as ventriculoperitoneal shunt placement and lumbar puncture and skull fracture with a persistent cerebrospinal fluid (CSF) leak. Congenital or developmental central nervous system (CNS) abnormalities also predispose affected patients to bacterial seeding of the CNS. These include neuroenteric fistula, intracranial cysts, and epidermoid or dermoid tumors, often with an associated congenital dermal sinus tract.

For ABM to occur, organisms must gain entrance into the subarachnoid space. On rare occasions, this occurs as a direct extension from a contiguous focus, such as sinusitis, mastoiditis, or otitis media. In a majority of cases, the bacterial organism gains access to the bloodstream and hematogenously seeds...
through inflamed capillaries within the choroid plexus. Most cases of ABM follow a progression of events. After exposure and nasopharyngeal colonization, invasion of the blood occurs. The organism can be recovered from the bloodstream in up to 90% of patients with CSF culture–proven bacterial meningitis.

If bacteria gain entrance into the subarachnoid space, they replicate. Bacterial cell wall constituents are liberated into the CSF. Host inflammatory mediators and cytokines, including interleukin-1, tumor necrosis factor, and platelet-activating factor, are produced and secreted by CNS macrophages and endothelial cells. As a result of an inflammatory response, vascular and parenchymatous cerebral changes occur. These include vasculitis, microthrombus formation, occlusion of venous sinuses, reduced blood flow, increased permeability of the blood-brain barrier, increased intracranial pressure, diffuse cerebral edema, and intracerebral hemorrhage.

**Clinical Features**

In three fourths of children ultimately diagnosed with ABM, the clinical presentation is subacute, evolving over 2 to 5 days. At onset, affected children typically exhibit a variety of symptoms and signs such as fever, malaise, decreased interest in surroundings, irritability, alteration in sleeping pattern, anorexia, nausea, vomiting, or diarrhea. These findings are nonspecific, seen with equal frequency in children who are suffering from trivial and self-limited illnesses. If the patient is examined early in the course, physical signs may be subtle or lacking.

Children with this insidious presentation have a better prognosis than patients with ABM who present with a rapid progression of signs and symptoms. In one fourth of children with ABM, an acute illness with manifestations such as vomiting, fever, and lethargy develops in less than 24 hours. In such patients, the diagnosis is rarely missed. Those with fulminant illness exhibit a higher risk for death as well as for both immediate and long-term complications.

In addition to the inaccessiveness of the offending organism, the other variable with the greatest impact on clinical expression is the age of the patient. As a rule, the younger and smaller the infant, the more nonspecific and ambiguous the symptoms and signs of ABM.

The cutaneous expression of ABM may be a helpful finding suggestive of specific organisms. Petechial and purpuric eruptions may suggest meningococcemia but also can be seen in cases of pneumococcal disease and *H. influenzae* meningitis. Herpes simplex virus (HSV) infections in the neonate are suggested by blisters or erosions in or around the eye, mouth, or skin. These lesions also may be seen in patients with bullous impetigo, candidal infections, varicella, listerioses, or syphilis.

**Neonatal Period (Up to the Age of 1 Month)**

The clinical findings with ABM in the neonate are nonspecific and may include altered vital signs, behavioral changes, neurologic aberrations, dermatologic lesions, and gastrointestinal manifestations (Table 173-1). In the first 30 days of life, patients who present to an ED with a temperature of 38°C (100.4°F) or higher are found to have serious bacterial illness and ABM in 4 to 15% and 1 to 2% of cases, respectively. The absence of fever does not eliminate the possibility of serious bacterial infection, because more than one half of neonates with meningitis are afebrile or exhibit hypothermia. Other vital sign changes include tachycardia, bradycardia, tachypnea, and apnea. Apnea with cessation of breathing for longer than 20 seconds may signify either seizure activity or a nonspecific medullary respiratory center dysfunction.

Neonates have a limited behavioral repertoire. Within that range, even subtle changes in behavioral patterns can reflect early meningeal involvement. Restlessness, listlessness, increased or decreased sleeping time, and irritability may be clues. Irritability in a neonate without meningeal invasion generally is alleviated by human contact. Increased irritability with cuddling should suggest the diagnosis of ABM. Neurologic manifestations of ABM in the neonate may include high-pitched cry, incessant cry, absent cry, or moan. A vacant stare, hypertonicity, trembling chin, or bicycling motion of the extremities suggests a seizure. Focal or generalized tonic-clonic activity, although possible, is less commonly seen. Nuchal rigidity occurs in less than 25% of cases of neonatal ABM. A bulging fontanel and diastasis of the sutures, both hallmarks of an increased intracranial pressure (ICP), are present in approximately 15% of the cases of neonatal ABM. Skin rashes are infrequent manifestations of neonatal meningitis. One clue may be generalized pallor accompanied by indistinctly outlined truncal patches of blue discoloration (livedo reticularis). Difficulty feeding and unusual stooling patterns are nonspecific gastrointestinal features. Nonprojectile vomiting may appear in the course of meningitis, becoming projectile only after ICP has increased. Increased stool volume, irritability during defeation, abdominal distention, hepatomegaly, and jaundice can develop with meningitis.

**One Month to 12 Months**

In young infants (younger than 3 months of age), symptoms of serious bacterial illness are similar to those in the neonate, but as the infant grows older, the social repertoire and motor capability expand, allowing for greater opportunity to assess...
for alteration in behavior or for signs and symptoms of bacterial meningitis. Nuchal rigidity, although not commonly present, is highly predictive for ABM in this age group. The absence of nuchal rigidity does not preclude the possibility of CNS infection; however, other signs often are present, such as poor tone, decreased interactivity, inconstancy, alteration in gaze and focus, and a weak cry.

One Year to 5 Years

The cardinal features in this age group are fever, headache, vomiting, and stiff neck. Obtundation and lethargy also are common findings with meningitis but are nonspecific. After the first year of life, neck stiffness with difficulty flexing the neck is reliably seen during the acute phase of meningitis. A patient rarely may exhibit torticollis.14 The clinician can attempt to elicit nuchal rigidity by forced flexion of the neck with the child in the supine position. However, this method is less reliable than attempting neck flexion with the child seated with both legs outstretched. Both of these maneuvers involve passive motion that many children voluntarily resist. More reliable methods that result in fewer false-negative and false-positive results involve active neck motion on the part of the child. In a toddler, a distracting object can be used to attract eye contact, and the active range of neck motion can be determined. Additionally, the neck stiffness that accompanies ABM may be displayed in both the prone and supine positions when the child’s shoulders are placed at the edge of the examining table and minimal support of the occiput or forehead is provided manually. Presence of Kernig’s sign (flexion of the hip 90 degrees with subsequent pain on extension of the leg) and Brudzinski’s sign (involuntary flexion of the hips and knees following passive flexion of the neck performed with the patient supine) is less reliable. Kernig’s and Brudzinski’s signs are seen in approximately 43% and 66%, respectively, of children with ABM.15

Older Than 5 Years

Headache, fever, stiff neck, and alteration of sensorium are common presenting signs and symptoms in children older than 5 years, as they are in the adult patient with ABM.

Diagnostic Strategies

Lumbar Puncture

Indications

Lumbar puncture is indicated in any child in whom bacterial meningitis is suspected. Patients to be considered as candidates for this procedure include those with classic signs and symptoms such as fever, stiff neck, and photophobia, but in infants and children, classic signs often are absent. In a study by Walsh-Kelly and colleagues, nuchal rigidity was present in only 27% of infants younger than 6 months of age with bacterial meningitis. By 12 months of age, 71% showed nuchal rigidity; this rate rose to greater than 95% by 19 months of age.16 Therefore, the decision to perform a lumbar puncture in children with suspected meningitis should be based primarily on the constellation of presenting signs and symptoms.

Nuchal Signs. A lumbar puncture should be performed in ill children who exhibit nuchal rigidity or a Kernig sign or Brudzinski sign and who have suspected meningitis. These three signs of meningeal irritation also can be seen in patients with parameningeal disease states other than ABM, so caution must be exercised in these cases.

Suspected Sepsis in Young Infants. A bacterial infection is the most likely etiologic disorder in any infant younger than 3 months of age who is ill.12 Current practice advocates that the possibility of severe bacterial infection must be pursued with an ill young infant. No distinguishing features differentiate sepsis from meningitis in this age group. Because 50% of neonates with acute meningitis are bacteremic at the time of the initial evaluation, and because an intracranial infection subsequently develops in 25% of bacteremic neonates, blood cultures and lumbar puncture should be undertaken concomitantly.17,18 In infants older than 1 month but younger than 3 months of age, history and physical examination, even if augmented with selective laboratory investigations (excluding lumbar puncture), may fail to identify those infants with a serious bacterial infection such as ABM. Thus, a lumbar puncture should be performed as part of the sepsis evaluation.19,20

Toxic Appearance. A lumbar puncture also should be considered in any case in which a global assessment of the child’s clinical condition suggests overall toxicity. Such observations include a blunted response to social overtures, poor perfusion, altered motor tone, and abnormal cry. Febrile pediatric patients of all ages with a toxic appearance have an increased incidence of severe bacterial infections, including ABM.11 Focal infections have been implicated as a source of dissemination of organisms into the CNS. Establishing an apparent infectious source for a particular presentation does not preclude the possibility of a more serious suppurative focus that may be intracranial.

If the patient exhibits clinical manifestations that are more severe than anticipated for an extracranial focus of infection, a lumbar puncture should be performed.

When obvious clues to the source of an apparent infectious process exist and an initial lumbar puncture yields negative findings in the face of increasing severity of illness, additional information can be obtained by repeating the lumbar puncture. The CSF composition may change from normal cellularity to marked pleocytosis within as little as 30 minutes.21 Thus, later reexamination of the CSF may be invaluable in establishing the nature of an occult intracranial infection.

Febrile Illness after Intimate Contact. All children who have prolonged and close physical involvement with persons found to have a serious bacteremic illness require prompt medical evaluation. In particular, fever developing after intimate contact with patients with meningococcal or Haemophilus disease is a strong indication for lumbar puncture in this age group.22

Febrile Seizures. Children 6 months to 5 years of age who have experienced a simple febrile seizure and who appear well (alert, active, playful) are extremely unlikely to have meningitis.23 Generally, patients who exhibit complex features of the febrile seizure are at increased risk for meningitis.

Lumbar puncture should be considered in patients who have characteristics that increase their risk for ABM or who show signs and symptoms of ABM. The historical features are age younger than 1 year, exposure to another child with meningitis or serious bacterial infection, and a physician visit within 48 hours before the febrile seizure. Children with febrile seizures who exhibit any clinical sign associated with increased risk for intracranial infection, including lethargy, decreased motor tone, doll’s eye sign, inability to fix and follow, decreased response to painful stimuli, nuchal rigidity, full fontanel, petechiae, and poor skin perfusion, should undergo lumbar puncture.

Fever and Petechiae. Trivial to life-threatening infectious disease can cause fever and petechiae. No current optimal strategy has emerged for evaluating febrile children with petechial eruptions. Well-appearing febrile children with localized petechiae, especially above the nipple line and with no purpura are
unlikely to have invasive bacterial disease. Patients at highest risk for invasive bacterial disease are more likely to appear ill or to have generalized petechiae and purpura or signs of meningeal irritation. In the high-risk group, unless contraindicated by coagulopathy, lumbar puncture should be performed to exclude concurrent meningitis.

**Sepsis Suspected in an Abnormal Host.** Immunocompromised pediatric patients are at risk for the development of both opportunistic infections and invasive illness from pathogens common to all children. Immunologically incompetent children may not exhibit the typical manifestations of intracranial infections, including nuchal rigidity. An immune-impaired child who experiences only a change in mental status, however, should be suspected of having meningitis. CSF parameters in these patients are less sensitive indicators of the presence of bacterial meningitis compared with normal host response to a bacterial invasion of the meninges. A lumbar puncture nonetheless should be performed in the process of excluding sepsis in a compromised host.

**Penetration of Dura.** Fracture through the paranasal sinuses or anterior or middle cranial fossa and penetrating nasal injury or instrumentation may lead to dural tears. Such defects constitute a potential portal of entry for microorganisms into the CNS. Evidence of CNS infection generally is seen within 2 weeks of the initial injury, but clinical manifestations may be delayed for years. Persistent CSF otorrhea or rhinorrhea may be encountered but is not a clinical prerequisite for posttraumatic meningitis. When patients with a recent or remote history significant for craniofacial trauma develop any constellation of symptoms suggestive of meningitis, lumbar puncture should be performed after a computed tomography (CT) scan.

**Acute Hearing Loss.** Hearing loss has been identified in up to one third of patients with ABM. Hearing impairment may be identified in the acute phase or become apparent only in the postmeningitic period. Of significance, hearing loss may precede the onset of systemic complaints and herald the appearance of meningitis. This is especially true for patients with an inner ear fistula or basilar skull fracture. Acute hearing loss should be an indication for lumbar puncture in patients with traumatic injury, which may have directly inoculated organisms into the labyrinth or basilar subarachnoid space, and in patients who have symptoms suggestive of meningitis.

**Contraindications**

Herniation of the temporal lobes through the tentorium or herniation of the cerebellar tonsils through the foramen magnum rarely occurs in patients with meningitis and increased ICP. Most children with ABM exhibit some mental status changes, but rapid onset and progression to deep coma (Glasgow Coma Scale score less than 8) usually reflect increased ICP, and lumbar puncture is contraindicated. Focal neurologic signs suggestive of an abscess are further contraindications to lumbar puncture in children.

**Positioning and Precautions**

When not contraindicated, emergency lumbar puncture with CSF examination should be performed to confirm a presumptive diagnosis of ABM (Box 173-1). Patients with suspected bacterial meningitis should have the procedure completed in the lateral decubitus position with spine flexed and knees drawn upward toward the chest, with shoulders and back perpendicular to the table. Opening pressure should be obtained if possible with the patient in this position. In circumstances in which opening pressure measurement cannot be obtained, an alternative position is sitting with the thighs flexed toward the abdomen.

In the stable monitored patient, the potential for complications is sufficiently low that sampling the CSF should be routine. Lumbar pain can be eliminated in all pediatric patients with the use of an anesthetic agent. Prevention of post–lumbar puncture cephalgia is enhanced by using smaller-gauge needles, restricting the sample fluid volume to 3 mL, and reinserting the stylet before removing the needle. The small risk of introducing bacterial skin flora is reduced with proper aseptic technique. Causing meningitis by performing a lumbar puncture in the course of a bacteremic illness is a theoretical concern but does not occur. The information obtained from the lumbar puncture outweighs this hypothetical risk.

**Standard Cerebrospinal Fluid Interpretation**

A standard CSF examination includes bacterial culture and Gram’s stain from tube 1, protein and glucose assessment from tube 2, and blood cell count from tube 3. In cases of culture-proven bacterial meningitis, up to 6% of patients have normal glucose and protein levels, few white blood cells, and a negative result on Gram staining. Patients who have received antibiotics before their first lumbar puncture merit special mention. Although the CSF can be sterilized after the administration of antibiotics in the ED, especially in cases of pneumococcal and meningococcal disease, the CSF profile often is unaffected for more than 12 to 24 hours after therapy.

**Glucose.** The CSF glucose concentration must be interpreted in relation to a concomitant serum glucose value. The normal steady-state CSF-to-serum glucose ratio is approximately 0.6. Hypoglycorrhachia, as defined as a ratio below 0.4, is characteristically found in cases of ABM with common pathogens and with *Mycobacterium tuberculosis*. Hypoglycorrhachia also may be associated with viral meningitis, although CSF glucose in such cases typically is normal.

**Protein.** The normal CSF protein range is 40 to 170 mg/dL in newborns and 15 to 45 mg/dL in children. Normal to modest elevations in protein concentration occur in the course of viral meningitis. Higher levels of protein are encountered with ABM. After a traumatic lumbar puncture, each 800 to 1000 red blood cells elevate the protein level by 1 mg/dL.

**Cellularity.** A representative cellularity profile is presented in Table 173-2. Unfortunately, these numbers have been largely derived from healthy or non–systemically ill children. The standard “panic values” that have been quoted often are greater than 2 standard deviations above the mean or are figures that are seen in only 5 to 10% of studied populations. Cellularity that exceeds these typical threshold values can be seen with conditions that indirectly influence the CNS; however, such cases should be considered to represent possible ABM and treated accordingly. These conditions include generalized seizure, shigellosis, and parameningeal focus of infections such as otitis media, sinusitis, and mastoiditis.
Patients with suspected sepsis or with foci of infection distant from the CNS such as pneumonia also may have increased cellularity. Classically in ABM, the total white blood cell count ranges from 1000 to 20,000/mm³. A white blood cell count of greater than 2000 is present in more than one third of cases of ABM. Significant pleocytosis also can accompany aseptic meningitis.

Of note, the practice of “correcting” for white blood cells in bloody CSF samples may have little scientific support. Underestimation of the white blood cell count may occur in the setting of culture-positive meningitis. Furthermore, consideration should be given to other illnesses, such as herpes simplex virus encephalitis, in which an increased number of red blood cells may be seen in the CSF.

In the first month of life, up to 60% of the cells in the normal CSF are polymorphonuclear leukocytes (i.e., neutrophils) (PMNs). Beyond 1 month in the normal state, not more than 3 PMNs/mm³ should be seen. Shortly after invasion of the meninges, white blood cells can be sampled from the lumbar space. Traditional teaching suggests that a rise in PMNs is characteristic of ABM. However, PMNs and bands may be present in patients with viral meningitis as well.

**Gram’s Stain.** The probability of visualizing bacteria on a Gram’s stain depends on the number of bacterial organisms present at the time of sampling. One fourth of the smears yield positive results with 10³ or more colony-forming units (CFUs) per milliliter; 60% of the smears show positive results with 10³ to 10⁴ CFUs/mL, and 97% show positive results with 10⁴ CFUs/mL. A positive result on Gram staining necessitates immediate antibiotic therapy, even in the absence of increased white blood cells and protein levels or decreased glucose level in the CSF.

**Other Cerebrospinal Fluid Tests**

**Antigen Detection.** Commercial antigen detection kits are available for detecting the common pathogens causing ABM. Microbial antigens in CSF are detected by coagglutination, latex agglutination, countercurrent immunoelectrophoresis, enzyme-linked immunosorbent assay, and centrifugation-augmented solid-phase immunoassay. Because antigens remain measurable after antibiotic treatment, antigen detection proves to be most effective in cases of partially treated meningitis or in patients in whom the CSF Gram’s stain and culture results are negative and ABM is strongly suspected. In any meningitic state, either untreated or pretreated, the CSF antigen detection kits are most sensitive when more than 500 white blood cells are present in the CSF. The antigens typically are present at high levels in the CSF for several days, even after parenteral antibiotics have been initiated. A positive CSF assay result provides reliable bacteriologic diagnosis. A negative antigen test result cannot exclude the diagnosis of ABM.

**Cytokines.** Assayed concentrations of C-reactive protein, various interleukins, tumor necrosis factor, and prostaglandins are elevated with ABM. These assays require sophisticated techniques and expensive equipment and take 5 hours to complete. For these reasons, the assays are of little utility in the ED setting.

**Polymerase Chain Reaction Testing.** The diagnosis of meningitis caused by HSV and enterovirus can be determined using PCR-based testing (for these organisms) in CSF. PCR assays for the detection of pneumococci are still experimental.

**Other Laboratory Testing Instruments**

The performance of other diagnostic tests in addition to CSF analysis should be guided by the clinical situation. Blood cultures are of proven value in the patient with ABM. A pretreatment blood culture will identify the organism recovered from the CSF in 86 to 92% of cases. Culture of specimens from body surfaces and orifices (e.g., nose and throat) is not helpful in identifying the causative pathogen. Positive results on culture from urine, stool, and pleural space samples substantiate systemic bacterial disease but do not ensure the presence of an intracranial infection with the same organism.

Determination of serum electrolytes and serum glucose may be helpful because changes in body water content and electrolytes may be a feature of ABM. The serum sodium level may be below 135 mEq/L in more than one half of the patients at the time of presentation. The blood glucose level should be estimated rapidly with a glucose oxidase tape, because hypoglycemia secondary to poor intake, vomiting, and metabolic derangements is a common complication. The estimated value should be confirmed with a serum sample submitted for electrolyte determinations.

No hematologic profiles can consistently identify pediatric patients with ABM; nevertheless, a complete blood count is warranted, because the total white blood cell count and platelet counts may aid prognostic risk assessment. Either thrombocytopenia or neutropenia at admission may be an ominous feature.

At the time of establishing the diagnosis of ABM in a moderately ill patient, arterial blood gas determination can be performed in selected cases as indicated by apparent hyperventilation or hypoxia or presence of signs of metabolic acidosis.

A Gram-stained smear of a petechial or purpuric lesion may reveal an offending organism causing systemic invasion. Serum C-reactive protein assay, erythrocyte sedimentation rate determination, and measurements of the various cytokines can be used to support the diagnosis of systemic bacterial infection. These tests yield nonspecific findings, however, and cannot be used to include or exclude a diagnosis of ABM. Elevated pretreatment values may be tracked to determine the most effective duration of therapy for ABM.

A urine specimen should be submitted for analysis. If the patient is pretreated with antibiotic agents, urine microbial antigen detection should be performed. Urine antigen detection may be positive in up to 87% of pretreated cases of ABM. A midstream clean-catch voided specimen or urine acquired by catheterization should be submitted. Urine from a bag specimen that is potentially contaminated by fecal material may yield false-positive results as a result of cross-reactivity with *E. coli* organisms.

**Radiology**

CT of the head should be performed when the clinical findings suggest subdural empyema, cavernous sinus thrombosis, lateral sinus thrombosis, cerebral hemorrhage, brain tumor,
brain abscess, or a parameningeal focus of infection. CT of the head without contrast should be performed on an emergency basis when the patient exhibits signs and symptoms of elevated ICP. Concern for raised ICP is warranted if the patient has cranial nerve palsy, absence of retinal venous pulsations, altered pupillary responses, papilledema, focal seizure, hemiparesis, ataxia, obtundation, persistent vomiting, decorticate or decerebrate posturing, or bradycardia unassociated with hypoxemia. A decision to image the head or other body parts (such as the chest) must not delay antibiotic administration for patients with ABM. If patients with a ventriculoperitoneal shunt demonstrate fever or signs of increased ICP, they also should undergo CT before tapping of the shunt for CSF.

**Differential Considerations**

Any of the manifestations of ABM can be expressed in a single patient. The most common presentation involves a combination of thermal instability, altered behavior, blunted mental status, and neck stiffness. The differential diagnosis for this constellation comprises infectious, metabolic, traumatic, and miscellaneous conditions (Box 173-2).

Many conditions cause a child to appear ill. Any infectious agent can cause clinical illness in children, particularly in the first months of life. Infants with infectious disease exhibit altered affect, including significant changes in mental status, strongly suggesting an intracranial pathologic process. Beyond infancy, children may exhibit a toxic appearance with any focal infection or with extensions from a primary focus leading to systemic invasion. In addition to infection, a change in mental status may be noted with endocrinopathy, hypoglycemia, electrolyte imbalance, metabolic disease, uremia, seizure, unintentional trauma, abusive head injury, intussusception, or exposure to toxins.

Nuchal rigidity provokes strong consideration of ABM. However, neck stiffness associated with altered mentation or neurologic deficit can occur with spontaneous intracranial hemorrhage, hemorrhage into brain tumor, epidural abscess, or brain abscess. Other causes of stiff neck include retropharyngeal abscess, peritonsillar abscess, and torticollis.

**Viral Meningitis**

In the first few years of life, the signs and symptoms of bacterial and viral meningitis can be indistinguishable. Beyond 1 year of age, a majority of children with viral meningitis have a relatively mild illness compared with children with ABM. Fever and retro-orbital or frontal headache are frequent symptoms of both diseases. Gastrointestinal disturbances such as anorexia, nausea, and diarrhea are more common with viral meningitis. Generalized myalgia also may be a feature, and patients often complain of neck ache or neck stiffness. However, reduction in active neck flexion is uncommon.

Modest elevation of PMNs in CSF specimens coupled with normal glucose level, normal to slightly elevated protein concentrations, and a negative result on Gram’s staining is anticipated with viral meningitis. These laboratory findings can confirm a clinical suspicion of viral meningitis. However, atypical features such as hypoglycorrhachia or significant pleocytosis can be found in 20% of encounters. This blurs the distinction between the two states and may alter management. Decision rules have been proposed to distinguish viral from bacterial meningitis, but their usefulness in clinical practice may be limited if they cannot identify every case of ABM. Nigrovic and colleagues, however, demonstrated a low risk (0.1%) for bacterial meningitis in children who lack the following criteria: positive CSF Gram’s stain, CSF absolute neutrophil count (ANC) of at least 1000 cells/µL, CSF protein of at least 80 mg/dL, peripheral blood ANC of at least 10,000 cells/µL, and a history of seizure before or at the time of presentation.

**Management**

Management priorities for ABM include airway protection, oxygenation, and volume resuscitation with monitored preservation of organ function. If the capillary refill time is delayed more than 2 seconds or the patient is hypotensive, the patient should be treated for shock. A bolus infusion of 20 mL/kg of normal saline or lactated Ringer’s solution should be provided while an indwelling urinary catheter is inserted. Up to 40 mL/kg should be provided as bolus infusions. If vital signs fail to stabilize after an infusion of 40 mL/kg of crystalloid solution and a urine flow of 0.5 mL/kg per hour or greater cannot be maintained, pressors should be given. In the patient without shock, an hourly infusion rate should be established that provides normal maintenance fluids. Fluid restriction, previously advocated, may be deleterious to the patient’s survival and neurologic recovery.

Beyond support of cardiopulmonary and hemodynamic status, initial management of ABM includes prevention of hypoglycemia, control of seizures, and administration of agents to maintain cerebral blood flow.

**Antibiotic Therapy**

Intuitively, it makes biologic sense to advocate expeditious antibiotic administration for the patient suspected to have

ABM. In reality, no studies have shown that a duration of any given time frame arbitrarily chosen to constitute an “excessive delay” affects morbidity or mortality; however, most experts agree that antibiotics should be administered within 1 to 2 hours of presentation in patients with suspected ABM. The timing of antibiotic administration in a patient with CNS syndrome compatible with ABM should be driven by the specifics of the clinical scenario. A conservative approach for children with suspected ABM consists of treatment with empirical antibiotics and hospitalization for observation. Strategies to stratify patients into low- and high-risk categories as a basis for appropriate management (i.e., to restrict hospitalization and antibiotic therapy to children with suspected bacterial meningitis) have been proposed. The following four categories are offered:

**Nontoxic, low-risk:** In a non-pre-treated patient with no evidence of systemic toxicity in whom the clinical picture is suggestive of viral meningitis, if the CSF indices confirm a clinical suspicion of viral meningitis (negative result on Gram’s stain, few white blood cells in the CSF, and normal CSF protein and glucose levels), antibiotics can be withheld in consultation with the patient’s primary care physician or a neurologist. Another option is to discharge the patient and schedule a repeat lumbar puncture within 12 hours after antibiotic therapy. These strategies are not without risk, because it often is difficult to distinguish viral meningitis from other infections such as Rocky Mountain spotted fever or ABM. If biochemical parameters or cytologic assessment findings resemble those in ABM, it is appropriate to begin empirical antibiotic therapy and hospitalize the patient for observation.

**Nontoxic, high-risk:** A patient with no evidence of toxicity but with high-risk historical factors (such as pretreatment with antibiotics, exposure to an invasive organism [H. influenzae or N. meningitidis], or age younger than 1 year) prompting increased concern for ABM requires blood culture and lumbar puncture for CSF analysis. If the spinal fluid is cloudy, antibiotic therapy should begin immediately rather than being withheld pending complete CSF analysis. In symptomatic patients exposed to a person with meningococcal infection, appropriate management consists of a full range of cultures, empirical antibiotic therapy, and hospitalization for observation until the results of all cultures are known, because the absence of meningitis does not rule out the presence of meningococcal disease.

**Critical, stable:** For the patient with classic signs of ABM who has a protected airway, adequate ventilation, normal perfusion, and no evidence of coagulopathy and is assessed as being in critical but stable condition, a blood culture with phlebotomy and a second culture with placement of an intravenous catheter, urinalysis and culture, blood chemistries, and a complete blood cell count are recommended, after which a lumbar puncture is performed. Antibiotics should be administered immediately after lumbar puncture and before the results of the CSF or other studies become available from the laboratory.

**Critical, unstable:** A patient with a CNS syndrome, abnormal vital signs for age, an unprotected airway, ongoing seizure activity, focal neurologic deficit, or coagulopathy is considered to be in critical and unstable condition. The risk for an adverse outcome as a result of diagnostic lumbar puncture is magnified, especially if the procedure is carried out before the patient is stabilized. Patients with clinical signs of increased ICP may experience fatal cerebral herniation (even if CT findings are normal) after a lumbar puncture.27 Two blood culture samples and blood and urine specimens for antigen detection should be obtained. Antibiotics should be administered and the lumbar puncture deferred.

ED antimicrobial treatment decisions are empirically based. The choice of agents should be based on knowledge of the prevalent organisms responsible for intracranial infections and the regional patterns of their antimicrobial susceptibility. The initial regimen chosen for treatment should be broad enough to provide coverage for the various pathogens typical for the age group being treated (Table 173-3).

In the newborn, no single antibiotic has bactericidal activity against all of the possible organisms commonly encountered. The most widely used combination therapy consists of ampicillin with an aminoglycoside or ampicillin plus cefotaxime, which is equally effective. For infants older than 1 month and younger than 3 months of age, in the absence of any evidence for presence of unusual organisms, conventional therapy is ampicillin and a third-generation cephalosporin. Beyond the age of 3 months, monotherapy with a third-generation cephalosporin provides adequate coverage, except in cases involving resistant strains of S. pneumoniae. When gram-positive cocci are identified on the CSF Gram’s stain, the combination of a broad-spectrum cephalosporin (e.g., cefotaxime, ceftiraxone) and vancomycin is now routinely recommended.39

### Steroid Therapy

The role of dexamethasone therapy for ABM has long been the focus of clinical interest. Consensus opinion suggests that for infants beyond 8 weeks of age, dexamethasone can mitigate some neurologic sequelae, particularly hearing loss in cases of ABM caused by H. influenzae. The beneficial effect, if any, of dexamethasone on morbidity and mortality caused by other bacteria is less well defined.7

Use of dexamethasone is not without risk. The most commonly reported deleterious effect of dexamethasone is gastrointestinal bleeding. The anti-inflammatory effects of dexamethasone have led to a false sense of clinical improvement, overshadowing the failure of the chosen antibiotic to eradicate an invasive organism. Reduced penetration of vancomycin with dexamethasone therapy has been

Steroid therapy is critical in the management of ABM. The role of dexamethasone therapy for ABM has long been the focus of clinical interest. Consensus opinion suggests that for infants beyond 8 weeks of age, dexamethasone can mitigate some neurologic sequelae, particularly hearing loss in cases of ABM caused by H. influenzae. The beneficial effect, if any, of dexamethasone on morbidity and mortality caused by other bacteria is less well defined.
demonstrated. As a potentially universal distribution of cephalosporin-resistant and penicillin-resistant S. pneumoniae approaches, reducing the penetrating effect of vancomycin may cause undue harm. In summary, it is best to adhere to the latest recommendations of the American Academy of Pediatrics (AAP) and limit the use of dexamethasone for the presumptive treatment of H. influenzae meningitis (a rare disease in the United States). Logistically, 0.15 mg/kg dexamethasone can be administered only after completion of the Gram’s stain interpretation or on finding a positive result on assay for H. influenzae antigens.

For optimal management, close observation is mandated for the patient with newly diagnosed and treated ABM. Vital signs, systemic perfusion, and level of consciousness can rapidly change. Complications from the disease state such as shock or seizure, or from interventions such as anaphylaxis or post–lumbar puncture herniation of cerebral contents, can be addressed only if the patient undergoes continuous monitoring.

**Acyclovir**

The issue of empirical treatment of a neonate or young infant (younger than 3 months of age) with acyclovir is controversial because identification of infected infants is challenging. Acyclovir should be administered in an ill or febrile infant with a history of maternal HSV infection, presence of vesicles on the skin, seizure, or focal neurologic signs. Use of acyclovir also should be considered in atypical presentations of sepsis or meningitis. The dose of acyclovir is 20 mg/kg IV every 8 hours for 21 days in full-term immunocompetent infants. Polymerase chain reaction assay for HSV should be performed in these cases.

**Disposition**

A child newly diagnosed with ABM is best managed by experienced physicians and nurses who are capable of addressing critical care needs. When available, the best resource is a hospital that can provide pediatric intensive care. If transfer of the patient to another hospital is necessitated by the lack of appropriate inpatient pediatric care, the composition, expertise, and equipment of the interfacility transport team are important. Accordingly, the relevant logistics are best worked out in advance of the actual patient encounter.

**SEIZURES**

**Perspective**

A seizure is a paroxysmal event characterized by a change in behavior of the patient; it is caused by abnormal and excessive activity of a group of cortical neurons. The clinical appearance of the seizure depends on the location and extent of brain involved. Epilepsy is defined as the occurrence of two or more unprovoked seizures.

Seizure disorders are among the most common neurologic disorders of childhood. In children, the incidence is the highest in the first year of life.

**Principles of Disease**

**Pathophysiology**

The young, immature nervous system is more susceptible to seizures. Early in development, excitatory activity predominates and inhibitory systems are undeveloped. This is known as the period of vulnerability. A paucity of synaptic connections and alterations in the synthesis of neurotransmitters also may play a role.

**Seizures and Brain Damage**

It is well known that children with epilepsy are at a significant risk for cognitive impairment and behavioral abnormalities. Distinguishing the relative contributions of the effect of the seizures themselves from the underlying CNS pathology and from the effect of anticonvulsants is difficult. A single prolonged seizure has been shown to damage the brain, particularly the temporal lobes and hippocampus. Additionally, a growing body of evidence points to the lasting effect of repetitive, brief seizures in early childhood.

**Clinical Features**

**Classification of Seizure Type**

One of the first priorities in evaluating a child with a seizure is to determine the seizure type and, if possible, the seizure syndrome. Seizures are classified into two main types: partial (consciousness is maintained) and generalized (consciousness is lost) (Box 173-3). In complex partial seizures, the patient experiences a change in level of awareness and may exhibit bizarre behaviors, including staring, lip smacking, wandering, or picking at clothing. In simple partial seizures, the patient experiences no change in mentation.

Generalized seizures may be convulsive or nonconvulsive. Absence seizures are generalized nonconvulsive seizures that consist of a brief arrest of consciousness and movement (i.e., for 5 to 10 seconds); no postictal drowsiness occurs. It may be difficult to differentiate a brief complex partial seizure from an absence seizure in children.

**Classification of Epilepsy: Epileptic Syndromes**

An epileptic syndrome is characterized by a specific triad of patient age at onset, seizure types, and electroencephalograpic features.
graphic findings. Identification of the epileptic syndrome provides information on prognosis and informs management decisions. Epileptic syndromes of infancy and childhood have been well described. Several of these syndromes are reviewed below (Box 173-4).

Infantile Spasms
Infantile spasms manifest during the first year of life and consist of rapid jackknife flexor or extensor spasms that appear in clusters. The electroencephalogram (EEG) shows hypsarhythmia, an abnormal pattern characterized by slow waves of high voltage and disorganized spike activity.

Approximately two thirds of children with infantile spasms have an underlying CNS disorder such as a congenital brain malformation or tuberous sclerosis. The outcome is poor. Only one half will attain remission of seizures, and the large majority will be mentally retarded. Treatment is notoriously difficult. In the United States, use of adrenocorticotropic hormone (ACTH) has traditionally been the treatment of choice, although prednisilone treatment is being used with increasing frequency.45 Reassurance and education constitute the mainstays of treatment.30

Febrile Seizures
A febrile seizure is defined as a seizure occurring in the presence of fever without CNS infection or other cause. To satisfy the criteria for a simple febrile seizure, the seizure must be generalized, last less than 15 minutes, and occur in a child between 6 months and 5 years of age who is neurologically and developmentally normal.49 Febrile seizures affect approximately 3% of children. Simple febrile seizures typically occur early in the course of the febrile illness. Almost half the children with a febrile seizure have a documented temperature of less than 39°C. Complex febrile seizures are diagnosed when multiple seizures occur during the same illness, seizures are prolonged (longer than 15 minutes), or the seizures have a focal component.

Thirty percent of children with a simple febrile seizure have a recurrence; of these, one half will have a third event.30 The younger the age at onset, the more likelihood of recurrence. Children with simple febrile seizures have a 2 to 3% chance of developing epilepsy (compared with a 1% rate of epilepsy in the general population). Children with complex febrile seizures have a significantly higher risk. Treatment with long-term anticonvulsants does not affect the later risk of epilepsy.51 Acetaminophen and ibuprofen have not been shown to decrease the likelihood of recurrence.

Rectal diazepam (Diastat) is safe and effective for terminating prolonged or repetitive febrile seizures and should be available for home use in the child with recurrent, prolonged febrile seizures.50 Long-term anticonvulsant use is rarely warranted.49 Reassurance and education constitute the mainstays of management.

Neonatal Seizures
The frequency of seizures is higher in the first month of life than at any other time in childhood.48 Neonatal seizures may be subtle: apnea, sustained eye deviation, chewing, or limb bicycling movements may be the only apparent changes. A high incidence of subclinical electrographic seizures has been described.50 Focal clonic movements usually are associated with an underlying structural lesion.

etiology of neonatal seizures

Although the causes of neonatal seizures are numerous, a relatively few etiologic disorders account for a majority of cases (Box 173-5). These include hypoxic-ischemic encephalopathy, intracranial infection, congenital brain malformation, cerebrovascular events, and metabolic disturbances, particularly hypoglycemia and hypocalcemia. Although inborn errors of metabolism are rare, early treatment can be lifesaving. A dose of 50 to 100 mg of pyridoxine will immediately stop the seizure and normalize the EEG in a neonate with the rare disorder of pyridoxine dependency.

Neonatal seizures also may predispose the affected infant to the development of cognitive and behavioral difficulties, as well as an increased risk of epilepsy, later in life. Ultimately, the prognosis is dependent on the etiology of the seizure.

**Status Epilepticus**

Convulsive status epilepticus constitutes a true neurologic emergency; it is associated with high morbidity and mortality rates that increase with duration of the seizure activity. Status epilepticus is defined as continuous seizure activity for 30 minutes or longer or occurrence of sequential seizures over a similar period without full recovery of consciousness between seizures. In clinical practice, any seizure lasting more than 5 minutes warrants intervention. Although the diagnosis of convulsive status usually is obvious, the duration of the seizures often is underestimated because the intensity of the jerking tends to diminish with time. The importance of careful observation cannot be overstated.

Status epilepticus occurs significantly more frequently in children than in adults, particularly in those younger than 1 year of age. Febrile illness is by far the most common precipitant of status epilepticus in children. Medication change, toxic ingestion, idiopathic epilepsy, metabolic derangements, and congenital abnormalities are the next most common. Although morbidity and mortality rates both are significantly lower than in adults, they are still significant at 30% and 4%, respectively. Complications in patients with prolonged status epilepticus may involve any and all organ systems.

Nonconvulsive status epilepticus is marked by an altered mental status. Patients may demonstrate confusion, unresponsiveness, abnormal motor movements, twitches, lip smacking, or automatisms. An EEG can confirm the diagnosis and should be obtained if nonconvulsive status is suspected. A benzodiazepine is the therapeutic agent of choice.

**Etiology of Seizures and Differential Considerations**

The first task of the ED evaluation is to determine whether the event in question was truly a seizure. Not all paroxysmal events are seizures (Box 173-6).

**Syncope** is one of the more common disorders mistaken for a seizure. This entity is characterized by a sudden, usually brief loss of consciousness and motor tone. It results from a reversible decrease in cerebral blood flow precipitated by cardiogenic or noncardiogenic causes. The patient usually complains of light-headedness and blurry vision and appears pale and sweaty, with clammy skin. Postictal confusion does not occur. Trembling and stiffening are common. Vasovagal syncope is quite common in otherwise healthy children and does not warrant further workup unless it is recurrent. Because vasovagal syncope generally occurs when the child is standing, cardiogenic syncope, such as from prolonged QTc syndrome, should be considered if the child is not standing at the time of the event.

**Breath-holding spells** occur in 4 to 5% of children, primarily between the ages of 6 and 18 months. Breath-holding spells are triggered by pain or emotional upset. During expiration, the breath is held and the child becomes cyanotic or pale; this may progress to loss of consciousness. The infant initially is limp but may exhibit a brief period of clonic movements or opisthotonos. The average attack lasts approximately 40 seconds.

**Migraines** may mimic seizures, particularly when accompanied by an aura, motor dysfunction, clouding of consciousness, or vomiting.

Disorders of sleep are distinguished by excessive daytime sleepiness or by disorder nighttime sleep. **Narcolepsy** is characterized by daytime sleep attacks, sleep paralysis, hypnagogic hallucinations (vivid hallucinations while falling asleep), and cataplexy (sudden loss of motor tone). Cataplexy may be mistaken for atonic or absence seizures. **Nocturnal enuresis** may

raise concern for a nighttime seizure with incontinence. Night terrors (pavor nocturnus) occur when the child suddenly appears to awaken and cries out. The child usually is unresponsive and inconsolable, and the event concludes with the child’s returning to sleep. Sleepwalking (somnambulism) and sleeptalking (somniloquy) are quite common among school-aged children.

Movement disorders may mimic seizures. Tics are rapid, repetitive, brief involuntary movements that occur intermittently and in flurries. Those most commonly seen are eye blinking and head shaking. Patients do not lose consciousness. Shudder attacks are uncommon but easily mistaken for seizures. They have been described as looking like the classic reaction to the chill experienced when cold water runs down the back. Paroxysmal choreoathetosis is an abnormal motor movement that may be spontaneous or triggered by the child’s movement.

Behavioral or psychiatric disturbances can manifest with behaviors that may appear epileptic. Panic attacks may be mistaken for complex partial seizures. The patient has a sudden sensation of intense fear accompanied by shortness of breath, dizziness, palpitations, sweating, choking, chest discomfort, and fear of dying. Psychogenic seizures are involuntary events that mimic seizures. Many children with psychogenic seizures also have epileptic seizures. Prolonged EEG monitoring may be necessary to differentiate an epileptic seizure from a psychogenic seizure.

Infants with gastrointestinal reflux may exhibit Sandifer’s syndrome, characterized by episodes of abnormal posturing, arching of the back, and torticollis.

**Etiology of Seizures in Children**

After the diagnosis of seizure is made, the seizure type and the etiology should be determined. Seizures can be divided into three main etiologic categories: acute symptomatic, remote symptomatic, and idiopathic seizures (Box 173-7).

Acute symptomatic seizures are provoked by an acute event. Febrile seizures are the most common cause of acute symptomatic seizures in children. Remote symptomatic seizures are due to an earlier, or remote, CNS lesion. Examples include head trauma (nonacute), congenital brain malformation, and any other chronic brain injury. Idiopathic seizures have no definable cause.

**Acute Symptomatic Seizures**

Meningitis should always be considered in any patient with seizures and fever, particularly children. A child whose mental status is normal both before and after the seizure is unlikely to have meningitis.

Hypoglycemia (defined as a blood glucose concentration less than 60 mg/dL in adults and less than 40 mg/dL in children) may cause acute seizures. Hyponatremia (serum sodium concentration less than 150 mEq/L) and hypernatremia (serum sodium greater than 150 mEq/L) are both associated with seizures. Hypernatremia most commonly is caused by dehydration.

Hypocalcemia and hypomagnesemia may lead to muscle spasms, paresthesias, hyperactive reflexes, weakness, tetany, and seizures. Hypocalcemic seizures are a common cause of neonatal seizures.

Post-traumatic seizures occur in as many as 15% of children after head injury. Impact seizures, occurring within 1 hour of a head trauma, are not associated with severe injury or with the later development of epilepsy. Early post-traumatic seizures (occurring within the first week of injury) may arise from cerebral edema or intracranial hemorrhage, laceration, or contusion. Phenytoin is effective in preventing early post-traumatic seizures but does not influence the development of late-onset epilepsy.  

Brain tumors cause a wide variety of symptoms depending on their location and the type of tumor. In children, tumors usually are infratentorial and therefore rarely cause seizures.

Stroke, both hemorrhagic and ischemic, may manifest with seizures. Congenital heart disease, sickle cell anemia, and...
homocystinuria are major risk factors for ischemic stroke in children. Vascular malformations such as arteriovenous malformations may cause hemorrhagic stroke.

Numerous drugs are known to cause seizures. Cyclic antidepressants, cocaine and other stimulants, antihistamines, and isoniazid are the most common agents of drug-induced seizures. Drugs that may be associated with seizures are summarized in Box 173-8. Seizures also may occur during drug withdrawal, usually within 48 hours of drug cessation. Drug withdrawal in the neonate is a significant issue. Withdrawal of benzodiazepines and barbiturates leads to an abstinence syndrome similar to ethanol withdrawal.

Reflex seizures are precipitated by a specific, identifiable stimulus. For example, viewing television and playing video games may induce seizures in photosensitive children.

Remote Symptomatic Seizures
Causes of remote symptomatic seizures include congenital brain malformations, neurocutaneous disorders, cerebral palsy secondary to brain lesions such as neonatal infarct, hypoxic-ischemic encephalopathy, or neonatal meningitis.

### Diagnostic Strategies

The initial diagnostic evaluation is directed toward determining if the event in question was indeed a seizure and, if so, identifying a specific underlying cause. If the patient arrives in the ED actively convulsing, immediate attention is turned to stopping the seizure.

A complete history is key to establishing the diagnosis of a seizure or epilepsy. Effort should be made to obtain a description from an eyewitness as well as an account from the patient himself or herself. The history should include:

1. **Events leading up to the attack:** What was the patient doing at the time? Did the patient become confused or complain of dizziness, a bad smell, flashing lights, or anything else?
2. **The event itself:** Did the patient get stiff or limp? Did the patient shake? Was there a loss of consciousness? Did the eyes or head turn in one direction? Was there incontinence? Having the observer demonstrate the movements can be very helpful.

**Diagnostic Strategies**

1. **Events leading up to the attack:** What was the patient doing at the time? Did the patient become confused or complain of dizziness, a bad smell, flashing lights, or anything else?
2. **The event itself:** Did the patient get stiff or limp? Did the patient shake? Was there a loss of consciousness? Did the eyes or head turn in one direction? Was there incontinence? Having the observer demonstrate the movements can be very helpful.
3. Events directly after the attack: Was the patient lethargic or confused? For how long? Did the patient remember the event? The occurrence of postictal confusion, headache, or fatigue can help differentiate a seizure from a nonepileptic event.61

4. Possible precipitants of seizures: Has there been recent fever, illness, rash, head trauma, drug use, or medication or supplement use?

5. Risk factors for epilepsy: Past history of meningitis, head injury, febrile seizures, congenital anomalies, or developmental delay, or a family history of epilepsy, as well as the presence of unusual birth marks may be elicited.

6. Previous history of abnormal movements, staring spells, or myoclonus: It is not uncommon for a patient with a first generalized tonic-clonic seizure to have underlying, undiagnosed absence epilepsy.

In a patient with known epilepsy, it is important to determine whether any doses of anticonvulsant have been missed. The general physical examination should look for signs of systemic disease that can cause seizure. Particular attention should be paid to detect evidence of meningitis, head trauma, drug use, dehydration, hypertension, and heart disease. Skin lesions, such as café-au-lait spots or hypopigmented nevi, may point to a neurocutaneous disorder. An abnormal head circumference may point to hydrocephalus or abnormal brain growth.

A careful neurologic examination also is an essential part of the ED evaluation of the child who has experienced a seizure. The examination should assess for signs of increased intracranial pressure, focal neurologic deficits, and developmental delay.

Management

The management of four categories of seizures—febrile seizures, afebrile seizures, neonatal seizures, and status epilepticus—is described next. Box 173-9 provides an overview of the approach to a child with a seizure.

Febrile Seizures

As mentioned earlier, a febrile seizure is defined as a seizure accompanied by fever without CNS infection occurring in children between 6 months and 5 years of age.62 In general, a child in this age range who had a brief seizure in the setting of fever and in whom the neurologic examination reveals no abnormalities can be assumed to have had a simple febrile seizure. The evaluation should be directed toward the diagnosis of the cause of the fever. According to the AAP recommendations, lumbar puncture is not necessary in children older than 18 months in whom the clinical findings are not suggestive of meningitis. Lumbar puncture should be considered in children between 12 months and 18 months of age and strongly considered in children younger than 12 months of age, because signs of meningitis can be subtle in this age group.63 EEG, blood workup, or neuroimaging generally is not required.

Afebrile Seizures

Laboratory Studies. Laboratory tests generally include determinations of calcium, glucose, urea, electrolytes, and magnesium.64 However, such studies are rarely abnormal in the child who is neurologically normal after a brief seizure.65 Toxicology screening should be considered if drug exposure is a concern. Anticonvulsant levels should be measured if the patient is on such medication and testing is available for a particular agent.

A lumbar puncture is mandated in the patient with an abnormal mental status or other signs of meningitis, regardless of whether or not fever is present. Most patients exhibit signs of an altered mental status in the postictal period. If the concern for meningitis is low, the clinician may opt to observe the patient over the next few hours; if the patient returns to baseline, a lumbar puncture often can be avoided. A prolonged seizure can cause a mild elevation of white blood cells in the CSF, presumably from a transient disruption of the blood-brain barrier. CSF should be sent for cell counts, protein, glucose, culture, and PCR for herpesvirus.

Radiography and Other Imaging

Consensus is lacking regarding the need for neuroimaging in patients who come to the ED after a first seizure. Emergent imaging should be performed in a patient with new focal deficits, persistent altered mental status, recent trauma, persistent headache, or partial-onset seizures.67 A witnessed generalized convulsion may have begun as a partial-type seizure before secondarily generalizing; it is important to question both the eyewitness and the patient about events at the onset of the seizure. Children with generalized unprovoked seizures and normal examinations usually do not require acute imaging. At follow-up evaluation, further evidence, such as a focal abnormality on the EEG, may indicate a need for neuroimaging, which can be done at that time. Children with a history of previously treated epilepsy do not need neuroimaging unless a change in clinical status occurs.

If imaging is indicated in the acute period, either CT or magnetic resonance imaging (MRI) may be used. Although MRI provides superior anatomic detail, the patient often needs sedation. Therefore, CT, which provides rapid imaging and is highly sensitive for detecting acute blood and fractures, is the imaging study of choice in the patient with head trauma or who is potentially unstable.

Special Procedures

The EEG is the most important laboratory test for evaluating the patient with a seizure. It rarely needs to be performed in the acute situation unless nonconvulsive status epilepticus is suspected. The EEG helps determine the seizure type, specific epilepsy syndrome, and risk for recurrence.65 Transient postictal slowing may occur for several days after a seizure.

Techniques such as sleep deprivation, hyperventilation, and photic stimulation enhance the sensitivity of the EEG. Ideally, all EEGs should be performed with the patient awake, drowsy, and asleep.

Treatment of Specific Causes of Acute Seizures. Hypoglycemia is treated intravenously with 25% dextrose, 2 to 4 mL/kg. Severe hypo-
natremia may be treated with the intravenous administration of 3% saline (4 mL/kg infused over 30 minutes) to raise the serum sodium level to 125 mEq/L. The remainder of the correction should occur slowly over the next 24 hours. Hypernatremia is corrected slowly over 48 hours. Hypocalcemia is treated with 10% calcium gluconate, 100 mg/kg IV; the patient should be on a cardiac monitor during the infusion. With most toxic ingestions that cause seizures, no antidote is available. Ingestions involving isoniazid constitute one exception; a dose of 1 mg of intravenous pyridoxine for each 1 mg of isoniazid ingested should be administered (5 mg is given for an unknown amount of isoniazid ingestion).

Patients suspected to have meningitis should be started on empirical antibiotic therapy (see Table 173-3). Additionally, the patient with altered mental status, focal seizures, and red blood cells in the CSF should be treated empirically for herpes encephalitis with acyclovir, 20 mg/kg per dose (15 kg per dose in children greater than 12 years) every 8 hours.

**Neonatal Seizures**

The common underlying causes of neonatal seizures differ from those in older children and adults (see Box 173-5). Initial diagnostic testing is summarized in Box 173-11. Glucose, calcium, magnesium, and electrolytes are sent immediately. If findings are normal, lactic acid, ammonia, and pH determinations should be considered. Lumbar puncture should be performed and fluid sent for cells, protein and glucose determinations, culture, and herpes PCR assay; clinical assessment for meningitis is not reliable in young infants. Imaging should be obtained. Head ultrasound scans may be obtained in a child who is not stable enough to be moved. Otherwise, head CT or MRI studies should be obtained.

Empirical antibiotic therapy should be started in affected infants (see earlier section on meningitis). Acyclovir (20 mg/kg per dose every 8 hours) is initiated if herpes encephalitis is a clinical concern. Hypoglycemia is corrected with 2 mL/kg IV of 10% dextrose solution. Hypocalcemia is treated with 10% calcium gluconate (1 mL/kg given over 5 to 10 minutes with heart rate monitoring and ongoing close inspection of the infusion site) or calcium chloride (20 mg/kg). Hypomagnesemia, which may be associated with hypocalcemia, is treated with a 0.25 mL/kg of 50% solution magnesium sulfate IM.

Phenobarbital, 20 mg/kg, is loaded; additional doses of 5 to 10 mg/kg may be given if necessary. Phenytoin and fosphenytoin are erraticly absorbed and have an unpredictable rate of metabolism in young infants; these agents are given only if seizures continue after phenobarbital. The dosage of fosphenytoin is 20 PE/kg. Benzodiazepines may be useful but are associated with hypotension and respiratory depression; they should be used with caution. Continued seizures may be treated with midazolam infusion.44 If seizures are refractory to medical treatment, empirical treatment with pyridoxine, 50 to 100 mg IV, is indicated. This will abort seizures in the rare child with pyridoxine dependency syndrome.

The diagnostic assessment of neonatal seizures is fairly straightforward and includes metabolic testing, lumbar puncture and CSF analysis, and neuroimaging (Box 173-11).

**Status Epilepticus**

Status epilepticus constitutes a true medical emergency. The patient is positioned to maximize ventilation and to prevent physical injury; the cervical spine must be protected if trauma cannot be ruled out. Oxygen is administered by nasal cannula or face mask, and a large suction catheter should be available to suction secretions. In the younger patient, the tongue may obstruct the airway; a nasopharyngeal airway will keep the tongue forward and improve respiratory status.

If the airway is compromised, respiratory failure occurs, or there is evidence of increased ICP, the patient should be intubated. Do not paralyze unless absolutely necessary, because this will mask signs of seizure activity. If needed, short-acting neuromuscular blockers, such as succinylcholine and vecuronium, should be used.

Monitor heart rate, blood pressure, and respiratory rate and pulse oximetry and treat hyperthermia with antipyretics and cooling blankets. Place an intravenous line and send blood samples for electrolytes, glucose (including rapid blood glucose), calcium, magnesium, renal function, liver function, antiepileptic levels (if indicated), and CBC. Urine should be sent for toxicology.68

Correct any metabolic abnormalities (see previous section on afebrile seizures). If necessary, an intravenous line may be used.

Begin anticonvulsant treatment as quickly as possible. The three most commonly used agents to treat convulsive status epilepticus are benzodiazepines, phenytoin, and barbiturates.56 Table 173-4 presents a summary of these medications. Benzodiazepines, particularly diazepam and lorazepam, usually are the initial drugs used in the treatment of status epilepticus. They diffuse quickly into the CNS, rapidly terminating seizure activity 70% of the time.69 The recommended pediatric intravenous dosage for lorazepam is 0.1 mg/kg (maximum 8 mg) given at a rate of 1 to 2 mg per minute; the recommended intravenous dosage for diazepam is 0.2 to 0.5 mg/kg (maximum of 10 mg) at a rate of 2 mg per minute. Hypotension, respiratory depression, and impaired consciousness may occur.

Rectal diazepam may be used if intravenous access cannot be obtained. The dosage is 0.5 mg/kg (maximum 20 mg). If Diastat, a rectal preparation of diazepam, is not available, the intravenous preparation may be instilled through a lubricated feeding tube inserted 4 to 6 cm into the rectum. Buccal and intranasal midazolam preparations are effective, although not yet commonly used; dosages are 0.4 mg/kg and 0.2 mg/kg, respectively.70

If the seizure continues, a second dose of benzodiazepine is given. If the seizure is ongoing, then fosphenytoin or phenytoin is loaded. Patients who already are on phenytoin should receive phenobarbital in a loading dose of 20 mg/kg.

Fosphenytoin is a water-soluble phosphate ester of phenytoin (prodrug) that is rapidly converted in plasma to phenytoin. Unlike phenytoin, fosphenytoin can be administered intramuscularly, can be administered with common intravenous solutions, and is substantially less cardiotoxic and less sclerosing to the vasculature. Additionally, it can be given three times more rapidly than is possible with phenytoin. Fosphenytoin produces plasma concentrations similar to those achieved for phenytoin in the same time period.

The standard loading dose of phenytoin is 18 to 20 mg/kg at a rate of 1 mg/kg per minute, not exceeding 50 mg per minute. The loading dosage of fosphenytoin is 18 to 20 PE (phenytoin equivalents)/kg at 150 mg per minute. Monitoring cardiovascular status, including blood pressure and ECG, is recommended with use of either medication. If hypotension results, the rate of infusion is decreased. If the seizure continues, phenobarbital is given in a loading dose of 20 mg/kg at a rate of 1 mg/kg per minute (maximum dose of 50 to 75 mg per minute). An additional dose of 10 mg/kg of phenobarbital may be given if necessary. Significant side effects include depressed consciousness, apnea, and hypotension; these complications are more pronounced in the presence of benzodiazepines.
When status epilepticus is refractory to these medications, any of several options may be tried. Concurrent EEG monitoring is very helpful at this point. The patient should be intubated if this has not yet occurred.

One option is use of inhalational anesthetics (e.g., thiopental, 4 mg/kg IV), although this is difficult in an ED setting and is rarely used. Levitoracetam (Keppra) is playing an increasing role in the management of status epilepticus. Another option is intravenous valproic acid (Depacon), 20 to 30 mg/kg (max 3 g), loaded at 5 mg/kg/minute. Valproic acid should not be used if underlying liver or metabolic disease is a possibility.

Midazolam is a safe and effective benzodiazepine that is extremely effective in terminating status epilepticus refractory to conventional agents. A bolus of 0.2 mg/kg is administered by slow intravenous injection, followed by infusion of 0.1 mg/kg per hour. The dose is increased every 15 minutes as necessary to a maximum of 10 µg/kg per hour. Tachyphylaxis may occur, necessitating high doses.

Propofol has been shown to be highly effective in the treatment of refractory status. An initial intravenous bolus of 1 to 2 mg/kg is followed by infusion of 2 to 10 mg/kg per hour. Propofol is contraindicated in children on the ketogenic diet.

Pentobarbital (10 to 15 mg/kg IV given over 1 hour, followed by 0.5 to 1.0 mg/kg per hour) also is effective. However, severe hypotension, cardiovascular toxicity, and postinfusion weakness are common complications.

Nonconvulsive status epilepticus is more difficult to recognize and often requires EEG for diagnosis. Treatment is with benzodiazepines or intravenous valproic acid.

Once the seizure has been effectively terminated, neuroimaging and lumbar puncture are indicated.

Disposition

Hospitalization is unnecessary for most patients after a first, brief unprovoked seizure so long as findings on the neurologic examination are normal and follow-up evaluation is possible. EEG and imaging studies can be done on an outpatient basis as necessary.

Children with simple febrile seizures can almost always be sent home. Warden and Hauser and their colleagues outlined advice to be given to families in the ED (Box 173-10).

A child with a prolonged febrile seizure, or multiple seizures, may be given a prescription for rectal diazepam (Diastat) (0.5 mg/kg PR rounded up to the nearest 2.5 mg, to a maximum of 10 mg in young children and 20 mg in older children) after consultation with the child’s neurologist or primary care physician. Instruct parents that Diastat is given only if a seizure continues beyond 5 minutes. Additionally, the parents should familiarize themselves with proper usage before an emergency. If the medication is administered, parents should call EMS for transport to the ED for further evaluation.

Children who have had a prolonged seizure or in whom the neurologic examination is not back to the child’s baseline should be admitted to the hospital. If adequate follow-up evaluation cannot be arranged, or if extreme parental anxiety is a factor, hospitalization also is recommended. Children with acute symptomatic seizures other than febrile seizures usually will need to be hospitalized for appropriate management of the underlying disorder (Box 173-11).

Initiating Anticonvulsant Therapy

The decision to start anticonvulsant prophylaxis must balance the risk for recurrence of seizure against the potential complications associated with long-term medication use.

Side effects of medication are common and include sedation, dizziness, blurred vision, ataxia, gastrointestinal disturbances, and cognitive and behavioral changes. Idiosyncratic reactions include hepatotoxicity, agranulocytosis, aplastic anemia, rash, Stevens-Johnson syndrome, and serum sickness.

Two thirds of children with a first unprovoked seizure never experience a recurrence. The risk of recurrence is increased

IO, intraosseous [administration route]; PE, phenytoin equivalent.
Febrile seizures occur in 2 to 5% of all children between the ages of 6 months and 5 years. These seizures may appear frightening to observers but generally are harmless. Simple febrile seizures often occur in the first 24 hours of the febrile illness and occur only once. If the seizure recurs, your child should be reevaluated. A febrile seizure may be manifested by body stiffening, twitching of the face and/or arms and legs, eye rolling, jerking of the arms and legs, staring, or loss of consciousness. Febrile seizures generally last less than a minute but can last up to 15 minutes.

Your child may appear not to be breathing and the skin color may become darker; if so, call 911 or emergency personnel and lay the child on the floor on his or her back. Do NOT place your fingers in the child’s mouth. Febrile seizures do not cause brain damage or paralysis. A child who has febrile seizures has only a slightly increased risk of developing a seizure disorder compared with a child who never had a febrile seizure. Febrile seizures tend to run in families. Febrile seizures can recur with subsequent febrile illnesses. Medicines generally are not given to prevent simple febrile seizures. Using medicines such as acetaminophen or ibuprofen for fevers has not been shown to prevent febrile seizures.

Advice to Parents About Simple Febrile Seizures

- Febrile seizures occur in 2 to 5% of all children between the ages of 6 months and 5 years.
- These seizures may appear frightening to observers but generally are harmless.
- Simple febrile seizures often occur in the first 24 hours of the febrile illness and occur only once. If the seizure recurs, your child should be reevaluated.
- A febrile seizure may be manifested by body stiffening, twitching of the face and/or arms and legs, eye rolling, jerking of the arms and legs, staring, or loss of consciousness.
- Febrile seizures generally last less than a minute but can last up to 15 minutes.
- Your child may appear not to be breathing and the skin color may become darker; if so, call 911 or emergency personnel and lay the child on the floor on his or her back. Do NOT place your fingers in the child’s mouth.
- Febrile seizures do not cause brain damage or paralysis.
- A child who has febrile seizures has only a slightly increased risk of developing a seizure disorder compared with a child who never had a febrile seizure.
- Febrile seizures tend to run in families.
- Febrile seizures can recur with subsequent febrile illnesses. Medicines generally are not given to prevent simple febrile seizures.
- Using medicines such as acetaminophen or ibuprofen for fevers has not been shown to prevent febrile seizures.

With concomitant Todd’s paralysis, neuroimaging or EEG abnormalities, developmental delay, a family history of epilepsy, a remote symptomatic seizure, or occurrence of the first seizure during sleep. If none of these risk factors is present, the 5-year recurrence risk is only 21%. No evidence is available to show that early treatment with anticonvulsant medica-

tions alters the later risk of epilepsy. Neither is there evidence showing that a single self-limited seizure causes neurologic sequelae, although a point of concern is that frequent brief seizures may indeed cause neurologic sequelae. Balancing the foregoing information, anticonvulsants generally are started only after a second unprovoked seizure and, if
possibility, after consultation with the patient's primary care provider or a neurologist. Keep in mind that a patient's first convulsion may not be the patient's first seizure. Absence seizures are commonly missed for long periods of time.

Patients with acute symptomatic seizures coupled with a risk factor for recurrence, such as cerebral hemorrhage, meningitis, or contusion, should be treated in the initial period with prophylactic anticonvulsants such as phenytoin or fosphenytoin. When the patient is stable, the decision to continue or discontinue treatment is made.

The choice of medication is dictated by the seizure type and syndrome and the side effect profile of the agent. Drug levels must be monitored with the older anticonvulsants, but most of the newer anticonvulsants do not necessitate monitoring.

Phenytoin, phenobarbital, valproic acid, and carbamazepine are all excellent medications for management of generalized and partial seizures. Phenytoin is a poor long-term choice in children because of the associated development over time of hirsutism, gum hyperplasia, and facial coarsening. Phenobarbital is rarely used in children older than 2 years of age because of the common occurrence of hyperactivity, sleep disturbances and lower intelligence quotient (IQ). Phenobarbital frequently is used in infants, however, because of its consistent absorption and excellent safety profile. Valproic acid is associated with a relatively high incidence of hepatotoxicity, particularly in children younger than 2 years of age; it is more effective in generalized seizures than in focal seizures. This leaves carbamazepine as the most likely choice for the management of partial epilepsy. Carbamazepine is available in a sustained-release preparation. Oxcarbazepine (Trileptal), a prodrug of carbamazepine, is available as well, and blood monitoring is not necessary with this agent.

Valproic acid commonly is the first-line agent for treatment of primary generalized epilepsy and is particularly useful with myoclonic and absence seizures. Carbamazepine and phenytoin can worsen absence seizures and myoclonus. Ethosuximide is quite effective for absence seizures, although it is not effective for convulsive seizures.

In the last decade or so, several new anticonvulsants have been approved by the U.S. Food and Drug Administration (FDA). These include gabapentin, felbamate, lamotrigine, topiramate, zonisamide, oxcarbazepine, levetiracetam and rufinamide. Their use is increasing in the pediatric population both for add-on therapy and for first-line monotherapy. Table 173-5 provides a summary of the commonly used anticonvulsants in children.

Decision to Withdraw Anticonvulsant Therapy

Many practitioners consider withdrawal of anticonvulsants if the patient has remained seizure-free for longer than 2 years.79 The likelihood of recurrence is increased if age at onset was more than 12 years, there is a family history of epilepsy, a history of atypical febrile seizures, remote symptomatic epilepsy, or EEG abnormalities. No consensus has emerged regarding the length of time of withdrawal; medication tapers lasting anywhere from several weeks to several months have been used.

HEADDACHES IN CHILDREN

Perspective

Headache is a common problem in children and adolescents. Even though a majority of patients have benign causes of headaches, which usually can be diagnosed by a careful history and physical examination, neuroimaging using CT or MRI or both may be necessary in selected cases. Proper diagnosis, treatment, and close monitoring of these patients are extremely important to ensure that no serious cause for the headache has been overlooked.

Studies of schoolchildren have indicated that 40% of children will experience a headache by 7 years of age and 75% will experience a headache by the time they are 15 and also that migraine (one of the most common causes of headache in childhood) occurs in 1% of children by 7 years and 5% of children by 15 years of age. Studies in the United States have found that the highest incidence (246 episodes per 100,000 person-years) of migraine headache is in boys 10 to 14 years of age.80

Principles of Disease

Several pathophysiologic theories have emerged to explain the mechanisms of headache. The vascular theory proposes that headaches are produced by dilation of intracranial or extracranial arteries. The change in vessel diameter triggers the auras before and the pain during a headache; the dilatation may be relieved by vasoconstrictive drugs, such as ergots. The neuronal theory proposes that headaches are due to a primary dysfunction of the brain; a wave of spreading neuronal depression is accompanied by decreased cerebral blood flow. Serotonin (5-hydroxytryptamine [5-HT]) may be a key mediator in this cascade of events. Serotonin agonists have been shown to relieve migraine pain. The trigeminovascular theory is an integrated hypothesis that combines elements of both theories. The trigeminal nerve makes synaptic connections with cerebral blood vessels, and the headache is an expression of the nerve-blood vessel interaction.81

Clinical Features

Headaches can be classified into five temporal patterns: acute, acute recurrent, chronic progressive, chronic nonprogressive, and mixed. An acute headache is new in onset and different from previous headaches; it can herald a broad range of conditions ranging from a viral illness to a subarachnoid hemorrhage.
Acute recurrent headaches can be expressed as periodic events separated by pain-free intervals. Chronic progressive headaches occur over weeks to months. They can signify serious medical disorders such as brain tumors or arteriovenous malformations. Chronic nonprogressive headaches usually occur for years and are classified as primary headaches (as opposed to secondary symptomatic headaches). Mixed headaches are a combination of acute recurrent headaches (migraine) superimposed on a pattern of daily chronic nonprogressive headaches.81,82

The primary goal of the ED evaluation is to differentiate symptomatic headaches from primary headaches such as migraine or tension headaches. The history is critical in investigating children’s complaints of headache and is the most important component of the evaluation for determining the correct diagnosis. Both the patient and family members should be asked about specific factors related to the headache. Rothner has created a patient questionnaire to generate a “headache database” from which clinicians can formulate a diagnosis, which is presented in Box 173-12.82

In addition to the important questions in Box 173-12, the clinician must focus on a detailed history of the neurologic system to identify any related symptoms (e.g., lethargy, ataxia, seizures, weakness, visual disturbances) and a general review of other organ systems. Warning signs of symptomatic headaches include recent onset, occurrence with straining or athletic endeavors, association with neurologic symptoms, change in headache pattern, nocturnal awakening, and bilateral occipital headaches. Additional information related to the past medical history (e.g., history of recent head trauma, neurologic or psychiatric disorders, hospital admissions, medications) also is important to obtain.

The physical examination, including vital signs, must be performed in a careful manner with particular attention to those findings unique to children. Height, weight, and head circumference should be compared with standard percentiles and the child’s previous growth history; a change in the rate or direction of growth may indicate the presence of an intracranial mass or hydrocephalus. Blood pressure also should be carefully measured, with use of age-appropriate cuff size and percentiles for age. The child’s head also should be auscultated for bruits associated with arteriovenous malformations, and a skin examination should be performed to look for stigmata of neurocutaneous disorders such as neurofibromatosis. The neurologic examination should begin with assessment of the child’s mental status, language, and level of consciousness and also should include assessment of cranial nerves; gait analysis; cerebellar, sensory, and motor function testing; and evaluation of deep tendon reflexes. The ophthalmologic examination should include pupillary reactivity, visual acuity, extraocular movements, and fundoscopy. Observation of interactions between the patient and family members also may provide clues to potential family problems, depression, or anxiety.

Headache Syndromes and Differential Considerations

The list of differential considerations for headache is extensive (Box 173-13).83

Acute Headache

The acute headache is a common problem in children and adolescents and accompanies many infectious processes. In the absence of other signs of CNS involvement (such as nuchal rigidity or alteration in level of consciousness), headaches in febrile children usually do not constitute evidence of CNS infection. In fact, nonspecific viral illnesses represent a majority of diagnoses in children presenting to the ED with an acute headache.

The most common cause of subarachnoid hemorrhage in young adults is a ruptured cerebral aneurysm. In younger children, rupture of an arteriovenous malformation that is near the subarachnoid space may cause subarachnoid and intraparenchymal hemorrhage. A common site of bleeding is the anterior cerebral artery with resulting pressure on the third cranial nerve. Varying degrees of ptosis, lateral deviation of the eye, and pupillary dilatation may be seen with this type of aneurysm.

If subarachnoid hemorrhage is suspected, CT of the head (non–contrast-enhanced) should be performed as soon as possible. If the CT scan does not show subarachnoid blood, a lumbar puncture must be performed, because head CT findings are normal 5 to 10% of the time, especially if only a small

**BOX 173-12**

**PATIENT QUESTIONNAIRE TO GENERATE HEADACHE DATABASE**

- Do you have more than one type of headache?
- How did the headache begin?
- Was there associated trauma or infection?
- How long has the headache been present?
- Are the symptoms worsening or staying the same?
- How often do the symptoms occur and how often do they last?
- Do the headaches occur at any special time or circumstance?
- Are the headaches preceded by warning signs?
- Where does it hurt?
- What is the quality of the pain? Is there pounding or a sharp sensation?
- Do you have any associated symptoms during the headache? Abdominal pain? Is there any nausea or vomiting?
- Do you stop what you are doing during the headache?
- Do you have any other medical problems?
- Are you taking other medications?
- Are there activities that make the headache worse?
- Does any medication make the headache better?
- Does anyone in your family have headaches?
- What do you think is causing your headache?

**DIFFERENTIAL DIAGNOSIS FOR HEADACHE**

- Aneurysm/arteriovenous malformation
- Congenital malformation (e.g., Dandy-Walker syndrome)
- Hydrocephalus
- Hematoma—subdural, epidural (acute), intraparenchymal
- Hypertension
- Infectious: viral illness, abscess, meningitis, encephalitis
- Metabolic
- Neoplasm
- Pseudotumor cerebri
- Subarachnoid hemorrhage; berry aneurysm rupture
- Toxic (medication, cocaine abuse, analgesia rebound)
- Trauma

amount of bleeding has occurred. The first and last samples taken in the lumbar puncture are examined for cells to eliminate the possibility of a “traumatic tap” (in which the number of red blood cells would be expected to decrease by the last tube) and the presence or absence of xanthochromia.

Localized acute headaches commonly are due to sinusitis, otitis media, dental disorders, or traumatic head injury. Dental disorders usually are accompanied by pain localized to the teeth, gums, or jaw. Temporomandibular joint dysfunction usually is associated with unilateral pain in the ear, jaw, or mouth. Headache associated with trauma must always be carefully investigated for the possibility of subdural or epidural hematomas, fractures, and leptomeningeal cyst—a “growing” skull fracture in a child 3 years of age or younger with a history of recent trauma. Ophthalmologic problems such as astigmatism, refractory errors, eye strain, or squint also are occasionally responsible for headaches in children.

Chronic-Progressive Headache

The chronic-progressive headache category is composed of disorders that cause progressive severe headaches in children. The development of increased ICP, which can be caused by brain tumors, pseudotumor cerebri, hydrocephalus, brain abscess, or intracranial bleeding, is a major problem in this category. Headache that awakens the child or is present on first awakening is a classic symptom of increased ICP. Impaired venous outflow in the supine position leads to excess fluid (blood, CSF, or edema) inside the skull, leading to increased pressure. Nocturnal or morning emesis also may suggest increased ICP. The physical examination may show symptoms or signs of increased ICP (papilledema, brisk reflexes, cranial nerve deficits, upturning toes in response to stimulation of the sole of the foot, decreased level of consciousness) as well as focal symptoms related to the location of the lesion (e.g., hemiparesis, ataxia, visual field deficits).

Headaches may be the first symptom of a brain tumor and as such occur with increasing frequency with age. In a recent study, 18% of 0- to 5-year-olds, 52% of 6- to 10-year-olds, and 68% of 11- to 20-year-olds who had brain tumors presented with headaches. Only 38% of primary brain tumors were diagnosed within the first month after the onset of symptoms. Most of these patients had at least three associated symptoms or signs, such as nausea, vomiting, visual effects, problems with walking, weakness, and changes in personality, school performance, or speech. The most common neurologic findings were papilledema, abnormal eye movements, ataxia, abnormal tendon reflexes, and abnormalities on the visual examination.

Clinical findings with pseudotumor cerebri (idiopathic intracranial hypertension) are secondary to the increased ICP and include papilledema, sixth cranial nerve palsy, and visual field obstruction. This condition is more common in females and younger children than in older age groups and is associated with obesity; use of outdated tetracycline; presence of otitis media or head trauma; use of vitamin A, steroids, birth control pills, or tetracycline; presence of menstrual irregularities or diseases that produce obstruction of the CSF pathways; and obstruction of the major venous sinuses. By definition, neuroimaging findings are normal. The lumbar puncture usually demonstrates elevated pressure, often greater than 20 cm H₂O, and normal CSF protein and glucose levels. Neuroimaging should precede lumbar puncture when increased ICP is suspected. Treatment can include diuretics and repeated lumbar puncture for incremental removal of CSF. Hydrocephalus may be related to a previous episode of meningitis, subarachnoid hemorrhage, or head injury or may be congenital.

Brain abscess can result from meningitis, head trauma, chronic otitis media and sinusitis, or septic embolization in children with congenital heart disease. Focal neurologic signs as well as fever and headache also may be present, but the patient may look surprisingly well. Before a lumbar puncture is performed and the opening pressure is measured, CT of the head with and without contrast enhancement should be performed to determine whether a mass lesion is present. CSF findings usually include a mild leukocytosis (10 to 200 leukocytes/µL), slightly elevated protein level, and normal glucose level. The CSF smear and culture usually do not reveal any organisms.

Subdural hematoma is associated with head trauma. Symptoms include those associated with increased ICP; seizures and other focal neurologic deficits also may be present. The diagnosis is confirmed by neuroimaging. Postconcussive headaches are common. These headaches can be severe and associated with dizziness and vomiting. Chronic progressive headache also can be a symptom of systemic diseases such as hypertension, collagen vascular disease, hypothyroidism, Lyme disease, mononucleosis, or inborn errors of metabolism.

Migraine Headache

The diagnosis of migraine is based on symptoms of recurrent headaches separated by pain-free intervals. A revised classification of migraine syndromes has been made for pediatric migraine (Box 173-14). Migraine headaches are classified primarily into migraine with and without an aura. Migraine without an aura, also known as common migraine, is the most common type of pediatric and adolescent migraine and includes the following criteria: more than five attacks that last 2 to 72 hours (untreated), plus a minimum of two of the following criteria—unilateral location, pulsing quality, moderate to severe intensity, and aggravated by routine physical activities—and accompanied by at least nausea and/or vomiting and photophobia and phonophobia.

The main features that differentiate the pediatric from the adult migraine headache are a shorter duration (1 to 48 hours), unilateral or bilateral pain, and the presence of either photophobia or phonophobia. In children, malaise, irritability, and dizziness commonly occur before the onset of the headache.

**Migraine with an aura**, previously known as classic migraine, is diagnosed when at least two episodes occur with the following criteria: (1) reversible symptoms arising from focal cerebral or brainstem dysfunction, (2) gradual development of the headache over more than 4 minutes or several symptoms that

---

**BOX 173-14 1998 REVISED CRITERIA FOR PEDIATRIC MIGRAINE WITHOUT AN AURA**

A. Five or more attacks fulfilling features B through D below

B. Headache attack lasting 1–48 hours (adults: 2–72 hours)

C. Headache has at least two of the following features:
   1. Either bilateral or unilateral (frontal/temporal) location (adults: unilateral)
   2. Pulsating quality
   3. Moderate to severe intensity
   4. Aggravated by routine physical activities

D. At least one of the following accompanies headache:
   1. Nausea and/or vomiting
   2. Photophobia and/or phonophobia (adults: both photo- and phonophobia)
occur in succession, (3) aura with a duration of less than 60 minutes, and (4) the appearance of a headache either before, simultaneously with, or within 60 minutes of the aura. In children, auras most commonly are visual, but sensory, motor, and psychic auras do occur. Hemiplegic migraine is characterized by the sudden onset of hemiparesis or hemisensory loss along with headache in the contralateral hemisphere. This type of migraine is seen more frequently in children than in adults. Even though symptoms usually last for hours or days, affected persons rarely are left with permanent deficits. Ophthalmoplegic migraine is characterized by severe unilateral eye pain and headache, followed by ipsilateral third nerve palsy of variable degree. Less commonly, the fourth and sixth cranial nerves may be affected. Basilar artery migraine, also common in children, manifests with a combination of visual symptoms (e.g., transient bilateral blindness, blurred vision) and visual hallucinations, vertigo, ataxia, loss of consciousness, and drop attacks. An acute confusional state consists of a change in personality, orientation, or behavior. The Alice in Wonderland syndrome includes perceptions of distortion in body images and shapes. Objects appear either much larger (macropsia) or smaller (micropsia) before, during, or after a headache.

Migraine variants are common. Abdominal migraine is characterized by recurrent abdominal pain, nausea, vomiting, and recurrent headaches. Benign paroxysmal vertigo is manifested as the sudden onset of vertigo, pallor, and nystagmus. Paroxysmal torticollis is defined as recurrent episodes of head tilt associated with headache, nausea, and vomiting. Of note, this is a diagnosis of exclusion. A child with a head tilt, vomiting, and headache must first be evaluated for a posterior fossa lesion. Ocular migraine is characterized by transient monocular visual blurring to blindness with bright flashes of light.

Epilepsy and migraine headache are distinct clinical syndromes, yet they share several characteristics such as aura, vertigo, nausea, pallor, loss of consciousness, drowsy postictal state, confusion, and transient focal neurologic deficits. The incidence of seizures is higher in patients with migraine than in the general population. The differentiation of these two clinical entities may be difficult in certain cases. Headache as the sole manifestation of a seizure is uncommon; however, headaches frequently may follow tonic, tonic-clonic, and brief complex partial seizures. Bilateral frontal throbbing headaches also may follow episodes of status epilepticus. Further neurologic evaluation including EEG may occasionally be necessary to try to distinguish between these two syndromes.

Chronic Nonprogressive Headache

Chronic nonprogressive headache commonly is seen in the adolescent population. Included in this category of headache are muscle contraction headache, depressive equivalents, and conversion headaches. The International Headache Society classification of headaches refers to these types of headaches as tension headaches. The symptoms of this type of headache include bilateral or unilateral; nonthrobbing, pressing, or band-like tightness of mild to moderate intensity; and the absence of nausea, vomiting, and aura. These headaches are further classified as either episodic (10 to fewer than 15 episodes/month lasting 30 minutes to 7 days) or chronic (more than 15 episodes/month for greater than 6 months).

Cluster Headache

Cluster headache is a distinctive headache syndrome more commonly seen in male patients. The syndrome rarely is seen in those younger than 10 years of age. Cluster headache is characterized by one to several attacks recurring each 24 hours, over several weeks to months, with headache-free periods between the cluster headaches. The headache-free periods may last from months to years. The pain is throbbing, severe, and unilateral; occurs over the same orbitotemporal region; and is associated with ipsilateral scleral injection, lacrimation, nasal stuffiness, and, less often, partial Horner’s syndrome. The pain lasts 30 minutes to several hours and can occur at any time of day or night.

Diagnostic Strategies

The diagnosis of a specific headache syndrome usually is determined by the history and physical examination. The primary goal of the ED evaluation is to eliminate the possibility of an intracranial lesion or serious extracranial pathologic condition. Skull radiographs and EEG are of limited value in this setting for the routine evaluation of children with chronic headaches.

Radiology

CT of the head and cranial MRI are excellent studies to evaluate patients with headaches. MRI is particularly useful in detecting abnormalities in the sella turcica, temporal lobes, posterior fossa, and cervicomedullary junction. MRI also is better at detecting arteriovenous malformations and low-grade tumors. In general, MRI provides superior anatomic detail compared with CT scan. However, a patient cannot be closely monitored during MRI. Therefore, CT is the modality of choice in the potentially unstable patient and for the detection of acute bleeding. Indications for the use of neuroimaging are presented in Box 173-15.

Laboratory and Special Procedures

Lumbar puncture occasionally is helpful in the evaluation of patients with headache. If the possibility of a mass lesion is a concern (as suggested by history of early-morning headaches

and vomiting or focal neurologic findings on physical examination), radiologic imaging should precede the lumbar puncture. The lumbar puncture is a necessary procedure to determine the presence of an infectious process, hemorrhage, or pseudotumor cerebri.

In a patient with suspected chronic progressive headaches, the headaches may be a symptom of a systemic disease. Laboratory tests that may be considered include CBC; urinalysis; erythrocyte sedimentation rate determination; antinuclear antibody assay; liver function studies; thyroid function studies; serum lipid assay and determination of serum magnesium, lactate, and pyruvate concentrations; and a Lyme disease titer.

**Management**

Treatment of primary childhood headaches requires attention to initial pharmacologic management as well as reassurance, removal of potential triggering factors, and initiation of a behavioral management program. A headache diary is important to help the patient identify potential triggers and the effects of medications. Common triggers include reduction in sleep, perimenstrual stress, missed meals, and foods such as caffeine, chocolate, processed meats, alcohol, red cheeses, red wine, monosodium glutamate, yeast extracts, nuts, figs, aspartame, and sauerkraut. Children with primary headaches are not hospitalized for care unless the diagnosis is uncertain and a serious cause of secondary headache is being considered.

**Migraine**

Treatment of migraine headache includes analgesics, vasocostricators, sedatives, triptans, antiepileptics, and other modalities. The patient should be placed in a quiet and safe environment. Simple analgesics and rest are the first line of treatment for patients with migraine as well as nonmigraine headache. These medications include acetaminophen (10 to 15 mg/kg per dose, 650 to 1000 mg for children 12 years of age and older) and the nonsteroidal anti-inflammatory drugs (aspirin, 10 to 15 mg/kg per dose, 650 to 1000 mg for patients 12 years and older; ibuprofen, 5 to 10 mg/kg/dose, 400 mg for those 12 years and older; or naproxen, 2.5 to 0.0 mg/kg per dose, 250 to 300 mg for those 12 years of age and older, to a maximum daily dose of 1250 mg).

For severe migraine episodes, more potent analgesics may be needed. These include ketorolac tromethamine (Toradol), a nonsteroidal anti-inflammatory which can be used parenterally in children who are vomiting (0.5 to 1.0 mg/kg per dose every 4 to 6 hours orally to a maximum dose of 60 mg); and oxycodone (0.05 to 0.15 mg/kg PO per dose every 4 to 6 hours, to a maximum dose of 5 mg every 6 hours). Combination medications, such as Fiorinal (butalbital, aspirin, and caffeine), Fioricet (butalbital, acetaminophen, and caffeine), and Midrin (isomethetepene, acetaminophen, dichloralphenazone) also are effective. The dose is 1 or 2 capsules in children older than 12 years of age. Caution should be used in prescribing these medications. In addition to producing an analgesic effect, these medications may produce alterations of emotional state, sedation, and psychological dependence.

In the adolescent population, vasoconstrictor drugs are used less commonly than in the adult population. Antiepileptic agents, although not as well studied in the pediatric as in the adult population, also may be considered. This group includes promethazine (in children: 0.25 to 0.5 mg/kg per dose IM or PR every 4 to 6 hours as needed; in adults: 12.5 to 25 mg every 4 to 6 hours as needed); metoclopramide (oral, IV 0.5–2 mg/kg per dose PO or IV q 4–6 hours (<10 mg); and prochlorperazine (in children weighing more than 10 kg or older than 2 years of age: PO or PR 0.4 mg/kg per 24 hours, divided, three to four times per day, or IM 0.1 to 0.15 mg/kg per dose, three to four times per day). Dystonic reactions with antiemetics are more common in children, so these agents must be used with caution in this population. Brousseau, in one of the few pediatric randomized clinical trials examining the efficacy of prochlorperazine with ketorolac for the treatment of acute migraine, found that by 60 minutes, a greater reduction in headache pain was obtained in the prochlorperazine group—even though 30% of patients in each group experienced some recurrence of headache symptoms.

Sumatriptan is a selective 5-HT1 receptor agonist that can mediate cerebral vasoconstriction and block inflammatory response and can be administered orally, intranasally, or subcutaneously. A recent review of medication trials of triptans in children with migraine highlighted the important finding that randomized clinical trials found no difference in outcome between the control and the experimental groups. In another pediatric study, however, a 78% response rate was obtained within 60 minutes using a single subcutaneous administration of 0.06 mg/kg. Finally, nasal sumatriptan (5 to 20 mg, repeated in 2 hours, to a maximum daily dose of 40 mg) has been shown to be effective in the adolescent population, along with oral preparations of 25 to 50 mg (repeated in 2 hours, to a maximum daily dose of 200 mg). Sumatriptan should be avoided in persons with cardiac disorders or hypertension and in patients who have received an ergot alkaloid in the preceding 24 hours. Other newer 5-HT1 agents such as zolmitriptan (Zomig) (at doses of 2.5 mg intranasally and 5 mg PO) compare favorably with sumatriptan. Cluster headaches, which are brief and may not respond to oral therapy, can be treated with inhalation of oxygen at 4 to 5 L per minute, the ergot alkaloid Cafergot, or sumatriptan.

The use of pharmacologic agents for prophylaxis in children with migraine headache requires careful observation and follow-up evaluation by the child’s primary care physician. The indications for use of these medications include more than two to three headaches per week and interference with lifestyle, particularly missed school days or inability to participate in social activities. In keeping with or perhaps reflecting the high spontaneous remission rate of childhood migraine, the placebo effect of many medications is very high. Controlled studies are extremely limited. Medications that have been used include propranolol (initiated slowly at a dose of 2 to 4 mg/kg per day, divided, three times a day; contraindicated in asthma patients), amitriptyline (initiated at a dose of 25 mg at bedtime for adolescents; a baseline ECG is recommended), calcium channel blockers, anticonvulsants (particularly valproic acid), cyproheptadine, and naproxen sodium. Cyproheptadine, valproic acid, and naproxen are available in liquid form, which is a valuable feature in the pediatric population. Methysergide should be avoided in children owing to serious side effects, including retroperitoneal fibrosis. Amitriptyline may be useful for adolescents with a diagnosis of migraine and muscle contraction headaches and in depressed children with headaches.

**PEDIATRIC ATAXIA**

**Perspective**

Ataxia comes from the Greek word _ataktos_ meaning “lacking order” and describes a pathologic abnormality of organization or modulation of movement.
Pathophysiology

Ataxia can be caused by congenital abnormalities or can be acquired. Congenital ataxia is associated with CNS abnormalities. Acquired ataxia can be acute, episodic, or chronic. The chronic ataxias are usually caused by inherited metabolic or genetic disorders. Most commonly, ataxia is caused by cerebellar dysfunction. Lesions in the corticospinal tract or dorsal columns of the spinal cord may also be causative.

Clinical Features

Most children with ataxia are seen in the first few days after onset, usually because of a refusal to walk, unsteadiness of arm movements, or the sudden development of a wide-based “drunken” gait. The history should identify any recent infection, injury, inadvertent drug ingestion, or other family members with the same problem. Mental status usually is normal in cases of postinfectious ataxia. If it is abnormal, the possibility of ingestion, acute disseminated encephalomyelitis, or stroke should be considered. Nystagmus is common if the cerebellum is affected. Papilledema or cranial nerve palsies suggest hydrocephalus or a lesion.

Differential Considerations

In children, 40% of ataxia cases are caused by acute cerebellar ataxia (Box 173-16). Boys are more commonly affected, with the highest incidence at ages 2 to 4 years. Seventy percent of patients have a history of recent illness with multiple causative agents, but varicella virus is the most common, with up to 26% of cases associated with varicella. Coxsackievirus and echovirus are other etiologic agents. The disease is thought to be due to an autoimmune phenomenon leading to cerebellar demyelination. Symptons and signs are maximal at onset, with the extremities more seriously affected than the trunk and ranging from unsteadiness and wide-based gait to complete inability to walk. Mental status is normal, and nystagmus is common. Fever and seizures are uncommon.

Acute postinfectious demyelinating encephalomyelitis can also cause ataxia and occurs in the recovery phase of a viral illness or vaccination. It is distinguished from acute cerebellar ataxia by alteration in consciousness and multifocal neurologic deficits as well as fever and the frequent occurrence of seizures.

Brainstem encephalitis can involve the cerebellum, causing ataxia in association with focal neurologic abnormalities and respiratory irregularities. Etiologic agents include Epstein-Barr virus, L. monocytogenes, and enteroviruses. Up to 32% of cases of acute childhood ataxia are due to drug toxicity, most commonly from ingestion of anticonvulsants, benzodiazepines, alcohol, or antihistamines and less commonly from exposure to organic chemicals or heavy metals. The ataxia usually is accompanied by lethargy, confusion, and inappropriate speech or behavior. Nystagmus may be present as well.

Approximately 45 to 60% of all childhood brain tumors arise in the brainstem or cerebellum and can manifest with slowly progressive ataxia. Acute decompensation can occur with the development of hydrocephalus or hemorrhage into the lesion.

Head injuries with cerebellar contusion or hemorrhage can cause ataxia. In patients with neck injuries, ataxia can be caused by vertebral artery dissection. Posterior circulation strokes are rare in children but should be considered after neck trauma with possible vertebral artery dissection as a cause for the ataxia.

The opsoclonus-myoclonus syndrome consists of ataxia, rapid chaotic multidirectional eye movements, and myoclonic jerks of the extremities, head, trunk, and face. Most commonly, this is seen as a presenting manifestation of neuroblastosoma or ganglioneuroblastoma in which the ataxia is thought to be due to a paraneoplastic autoimmune phenomenon involving cross-reactivity of tumor and cerebellar antigens. Spontaneous vertebral artery dissections also have been reported in children without a known history of trauma.

Ataxia can be seen in patients with basilar migraine and can be associated with vertigo, hemiparesis, cranial nerve dysfunction, nausea, vomiting, or headache.

Loss of sensory input to the cerebellum can cause a sensory ataxia. Clinical manifestations will include a Romberg sign, decreased deep tendon reflexes, and impaired proprioception and vibration sense. Fifteen percent of patients with Guillain-Barré syndrome have sensory ataxia. In the Miller-Fisher variant of Guillain-Barré syndrome, the triad of ataxia, areflexia, and ophthalmoplegia of vertical gaze is characteristic.

Transient ataxia can be present in the ictal or postictal phase of seizures. Inborn errors of metabolism also can manifest with ataxia, which can develop acutely or be intermittent, depending on dietary intake or the presence of other illness. Such disorders should be considered when ataxia is accompanied by lethargy, encephalopathy, vomiting, diarrhea, or unusual body odor. Defects in urea acid cycle enzymes called aminocacidurias, as well as defects in pyruvate and lactate metabolism, can cause such signs and symptoms. Other inherited disorders such as Niemann-Pick, Tay-Sachs, and Wilson’s diseases also can cause ataxia. Repeated attacks of ataxia also can be the presenting manifestation of multiple sclerosis.

A discussion of all of the genetic disorders that can cause ataxia would be too vast to be included here, but the two most common genetic disorders are Friedreich’s ataxia and ataxia telangiectasia.

Friedreich’s ataxia is a disorder of autosomal recessive inheritance characterized by progressive gait and limb disturbance. It is caused by mutation in the gene encoding a mitochondrial protein, frataxin, that results in loss of gene function. Affected patients demonstrate dysarthria, lower limb areflexia, and proprioceptive sensory loss and high-arched feet (pes cavus). Most patients are unable to walk by the age of 30 years.

most common cause of death is cardiomyopathy causing intractable congestive heart failure, as well as respiratory compromise from severe kyphoscoliosis.96

**Ataxia telangiectasia** is a disorder of recessive inheritance caused by gene mutation that manifests as a truncal ataxia in infancy that leaves most patients wheelchair bound by the age of 12 years. Oculocutaneous telangiectasias usually appear by age 3 to 5 years. These patients also demonstrate dysarthria, nystagmus, dystonic posturing, myoclonic jerks, and accelerated aging. They have deficient IgA and decreased IgE and IgM levels. They suffer from frequent sinus and pulmonary infections, as well as a 50- to 100-fold risk for development of leukemia and lymphoma. The mean age at death from this disorder is 20 years.99

### Diagnosis

The key to making the diagnosis is taking a complete history and performing a thorough physical examination. In particular, testing cerebellar function by looking for dysmetria and dysdiadochokinesia is helpful.100 Urine and serum toxicologic studies are the laboratory tests most likely to prove diagnostic. CT and MRI findings usually are normal in patients with postinfectious ataxia, but demyelination, tumor, hydrocephalus, or traumatic injuries may be identified. CSF analysis may show mild pleocytosis or lymphocytosis in acute postinfectious ataxia; findings are normal in most other cases. EEG is recommended for patients with altered consciousness and fluctuating clinical signs. A pattern of epileptiform discharges or slowing is seen in 66% of children with acute cerebellar ataxia. EEG also can diagnose nonconvulsive or convulsive seizures. The EEG pattern is normal in the opsoclonus-myoclonus syndrome. Electromyography may be helpful if sensory ataxia is suspected and may help diagnose Guillain-Barré syndrome. Urinary catecholamines can be assayed to diagnose neuroblastoma. Testing for newborn errors of metabolism includes a CBC; liver function tests; measurement of blood ammonia, lactate, pyruvate, and ketone levels; and determination of acid-base status. Other tests include plasma and urine amino acid assays, urine organic acid assay, determination of serum biotinidase level, and CSF lactate assays. Genetic or other specialized testing also may be required. In the absence of developmental delay or positive family histories, however, these investigations for inborn errors of metabolism are unlikely to be helpful.100

### Management

Children with ataxia usually require hospital admission for a complete evaluation. Consultation with a pediatric neurologist should be sought for patients in whom the cause of the ataxia is not evident on the ED evaluation.

Most children with acute cerebellar ataxia recover completely. Improvement is seen within a week and complete recovery in 3 months for 50% of children. Sixty-six percent to 90% recover completely. Some children exhibit persistent gait disturbances, ataxia, and delayed speech development. Evidence is lacking for improved outcomes with immunosuppressive therapies. Recovery is slower from acute postinfectious demyelinating encephalopathy. Corticosteroids may hasten recovery. Relapse can occur in up to 10% of children. Most children recover fully, but some are left with significant permanent sequelae. Brainstem encephalitis should be treated with broad-spectrum antibiotics effective against *L. monocytogenes*; acyclovir should be included to provide coverage for varicella and other viruses until an organism is discovered. Patients with Guillain-Barré syndrome will need to be hospitalized and may require intravenous immunoglobulins and plasmapheresis to reduce circulating antibodies.

### PEDIATRIC VERTIGO

**Perspective**

Vertigo is defined as an illusion of movement, a sensation that the external world is revolving around an individual (objective vertigo) or that the affected person is revolving in space (subjective vertigo). Vertigo is well recognized to occur in the pediatric age group and has many potential causes.

**Pathophysiology**

Disease processes that affect the balance of the vestibular, visual, and proprioceptive systems can cause vertigo by impairing the neural activity of the vestibular nucleus. Diseases of the ear, the eighth cranial nerve, the brainstem, or, rarely, the eye all can lead to vertiginous symptoms. Vertigo is characterized as *central* or *peripheral*, depending on whether the cause is in the CNS or not.

**Clinical Features**

Vertigo often manifests with dizziness. There may be a history of sudden falls, grasping for support, or unwillingness to move. Review of symptoms should include those related to the ear, such as otalgia, hearing loss, or tinnitus. Other important historical features that should be asked about include headache, loss of consciousness, head trauma or barotrauma, and family history of migraine and seizure disorders.

**Diagnostic Strategies**

To determine the cause of vertigo, patients can be divided into those who have hearing loss and those who have normal hearing. In the group with hearing loss, further characterization of the loss as conductive or sensorineural in character and identification of the presence of trauma, and whether the causative disorder involves the CNS or the peripheral nervous system from the labyrinth or eighth cranial nerve, will help in diagnosis (Fig. 173-1).

**Differential Considerations**

Although not as common in the pediatric age group as in adults, vertigo has many potential causes (Box 173-1).101 It usually is helpful to separate those conditions that cause vertigo into those with and those without associated hearing loss.

Benign paroxysmal vertigo of childhood is defined by the repeated occurrence of vertiginous episodes lasting seconds to minutes, with occasional vomiting, which usually remits spontaneously for months to years. The most frequent cause of benign paroxysmal vertigo of childhood is a migraine headache,99 with vertigo occurring as the aura of an episode.109

Patients with basilar artery migraines also present with vertigo; hemiparesis; ataxia; palsies of the third, sixth, or seventh cranial nerve; drop attacks; and blindness in various combinations followed by migraine headache. Children with benign paroxysmal vertigo of childhood or basilar migraines usually have a family history of migraine headaches.101

Benign positional vertigo is rare in children, and the earliest age at which it has been reported is 11 years.101 It is believed to be due to an otoolith that has moved out of its normal position in the utricle and can occur spontaneously as well as after trauma.

Ménière’s disease, a syndrome with a combination of vertigo, fluctuating hearing loss, and tinnitus, is responsible for 1.5 to 4% of cases of pediatric vertigo.102,103

Vestibular neuronitis manifests with vertigo without hearing loss. A viral infection is thought to be the cause. Sixty percent of patients have a preceding cold. It manifests with severe vertigo that resolves in a few days, after which the child will have vertigo only with rapid head movements, which persists for weeks or months until central compensation occurs.104

Labyrinthitis is an inflammatory process involving the inner ear membranous labyrinth. It manifests with vertigo, hearing loss, and tinnitus. Viruses such as cytomegalovirus, rubella virus, and rubeola virus are etiologic agents. Bacterial labyrinthitis also can occur, usually associated with meningitis.105 Lyme disease and syphilis each may cause vertigo if the inner ear is affected.105 Neurofibromatosis can manifest with vertigo if it involves the superior vestibular nerve. Café-au-lait spots or syphilis, as the physical examination dictates.101,105 The physical examination including otologic and neurologic evaluation is important. Looking for nystagmus and cerebellar testing are especially critical. Having the child hop as well as stand from a seated position on the floor with eyes open and closed may reveal vestibular dysfunction. Looking for physical signs of other disease processes such as café-au-lait spots in neurofibromatosis may aid in diagnosis. If a Valsalva maneuver or Hennebert’s sign, which consists of nystagmus for several days followed by improvement but may reoccur intermittently with certain head positions. Displacement of an otoilith is thought to be responsible.106

Temporal bone fractures (especially transverse) also may cause vertigo by injury to the eighth cranial nerve or the otic capsule. It also may cause sensorineural hearing loss.107 Whiplash injuries to the neck also can cause vertigo, with up to 50% of patients experiencing hearing loss or tinnitus. Post-traumatic migraine and seizures also can cause vertigo and occur in 5 to 7% of patients with closed head injuries.106

Perilymphatic fistula manifests with sensorineural hearing loss of sudden onset. It frequently is associated with congenital cranial deformities and congenital abnormalities of the ear. However, barotrauma (flying, extreme coughing, retching, or straining) or direct trauma also can be a cause. There is leakage of fluid from the oval or round window into the middle ear. Having the patient perform a Valsalva maneuver may precipitate vertigo. Hennebert’s sign, which consists of nystagmus and vertigo after negative pressure is induced in the ear by a pneumatic otoscope, may be a feature.101 Treatment usually consists of surgical repair.

Ocular disorders such as convergence insufficiency, strabismus, and amblyopia have been reported to cause a sensation of vertigo, and treatment of these disorders will eliminate the vertigo in children.107

### Diagnostic Strategies

For most patients, the final diagnosis for the cause of the vertigo may not be able to be made in the ED. A complete physical examination including otologic and neurologic evaluation is important. Looking for nystagmus and cerebellar testing are especially critical. Having the child hop as well as stand from a seated position on the floor with eyes open and closed may reveal vestibular dysfunction. Looking for physical signs of other disease processes such as café-au-lait spots in neurofibromatosis may aid in diagnosis. If a Valsalva maneuver or Hennebert maneuver initiates vertigo, the cause probably is a perilymphatic fistula.

Vertical nystagmus is always from a central cause. Nystagmus from peripheral causes tends to extinguish or diminish after rapidly repeated stimulation, whereas central nystagmus does not. Helpful laboratory tests in the vertiginous patient include glucose and electrolyte assessment, thyroid function tests, and viral titers or serologic studies (e.g., for Lyme disease or syphilis), as the physical examination dictates.101,106 The Hallpike-Dix positioning maneuver may help to diagnose benign positional vertigo.104 A CT or MRI scan is indicated only in cases of central vertigo.

### Management

Management of the vertiginous patient depends on the underlying cause, which may not be evident in the ED.108 For acute symptomatic relief, vestibular suppressants such as meclizine or diazepam may be helpful. Otoliths causing inappropriate stimulation may be restored to their proper place by Epley’s maneuver.101,106 Vestibular rehabilitation exercises that encourage patients to move the head while viewing a stimulus may assist in vestibular adaptation and reduce symptomatology.101 Follow-up including examination, testing, and treatment by a neurologist or an otolaryngologist for vertiginous patients is

recommended. Highly symptomatic children may need to be admitted to the hospital.

**SYNCOPE**

**Perspective**

*Syncope* is defined as a sudden, reversible, typically brief loss of consciousness and muscle tone (between 20 and 60 seconds) that usually reverses without intervention. The exact incidence of syncopal episodes is not known, but 15 to 25% of children and adolescents experience one episode by young adulthood.\(^{109,110}\) The peak incidence occurs between 15 and 19 years of age, and females are affected more frequently than males. The presentation of these events can be quite frightening to the patient and those who witness them (parents, teachers, peers, coaches). Gordon and coworkers found that in a group of pediatric patients presenting to the ED, a mean of six diagnostic tests were performed per patient, 40% of these patients were admitted to the hospital, and total charges averaged $3000 per patient, yet significant pathologic conditions were found in less than 10% of the patients.\(^{112}\)

**Principles of Disease**

The causes of syncope can be divided into autonomic, cardiac, and noncardiac. The most common cause of syncope is reflex syncope (also called autonomic, vasovagal, neurocardiogenic, or vasodepressor syncope or fainting). Venous pooling and decreased preload associated with prolonged standing normally are compensated for by reflex tachycardia and increased sympathetic tone. Patients who are prone to syncope demonstrate a cardioinhibitory response causing bradycardia or a vasodepressor response causing hypotension or, most commonly, a combination of both. Patients with cardiac syncope have decreased CBF resulting from poor cardiac filling or contractility, elevated afterload, or cardiac arrhythmias.

**Clinical Features**

Patients can experience syncope during intercurrent illnesses, with mild dehydration, during menstruation, or after vigorous exertion. In those with situational syncope, typical triggers may include emotion, pain, hyperventilation, shower, cough, swallowing, urination, or defecation. Before the event, they may experience dizziness, light-headedness, weakness, nausea, chest discomfort, palpitations, blurred vision, headache, tremulousness, and anxiety. After the event, loss of consciousness is brief (usually for less than 20 seconds), and the patient is described as ashen-appearing, with sweating and coolness of the extremities.\(^{113}\) Other examples of conditions associated with neurally mediated syncope are postural orthostatic tachycardia syndrome, chronic fatigue syndrome, and pandysautonomia.\(^{114}\) Patients with postural orthostatic tachycardia syndrome and pandysautonomia experience orthostatic palpitations rather than straightforward syncope, do not appear healthy between events, and complain of fatigue and exercise intolerance. Patients with pandysautonomia also exhibit thermoregulatory impairment, sweating, and bowel dysfunction.\(^{114}\)

Although cardiac causes of syncope are rare, they can be life-threatening and should be suspected when the episode occurred during exercise or physical activity. Noncardiac causes include seizures. Helpful features to differentiate seizures from syncope include the following: seizures usually occur in a supine rather than an upright position, convulsions occur before rather than after the loss of consciousness, and warm, flushed or cyanotic-appearing skin, rather than pale and sweaty skin, is characteristic.

**Diagnosis**

Evaluation of the patient begins with obtaining a description of the event, previous episodes, and past personal and family history. A detailed description of the event and particular note of any presyncopal symptoms or signs such as sweating, nausea, pallor, visual changes, or onset with a rapid change in position can suggest vasovagal syncope. A thorough physical examination with determinations of orthostatic heart rate and blood pressure performed with the patient in supine, sitting, and standing positions and a detailed neurologic examination are essential. A baseline electrocardiogram should be obtained to rule out structural heart disease or an arrhythmia. If the history, physical examination, and electrocardiogram are typical for a neurally mediated event, further testing is not usually required. Family history of sudden death, early infarction or arrhythmia, previous personal history of fatigue with a known arrhythmia or heart defect, syncope preceded by chest pain or palpitations, occurrence of syncope during exercise, occurrence of syncope without a prodrome, recurrent syncope (more than two or three episodes), and a syncopal event with neurologic sequelae all warrant additional testing.\(^{115}\)

**Differential Considerations**

Cardiac causes of syncope may be life-threatening. Such disorders include underlying structural abnormalities of the heart, such as cardiomyopathies (hypertrophic, dilated, and restrictive), postoperative congenital heart anatomic changes (Mustard, Fontan), congenital coronary artery abnormalities, myocarditis, aortic stenosis, and pulmonary hypertension. Other cardiac abnormalities include those classified as electrical disorders, such as long QT syndrome, Wolff-Parkinson-White syndrome, atrioventricular block, idiopathic ventricular fibrillation, or Brugada’s syndrome. Patients with an underlying cardiac abnormality merit further investigation, which may include 24- to 48-hour Holter monitoring, an echocardiogram, or exercise stress testing. Tilt-table testing can be used after diseases such as myocarditis, hypertrophic cardiomyopathy, and long QT syndrome have been ruled out, because such testing in this subgroup can have fatal consequences.

Common noncardiac causes of syncope include neurologic disorders (seizures, migraines, tumor, and vertigo), breath-holding spells, electrolyte abnormalities (hypoglycemia), hyperventilation (hypocapnia), endocrinopathies, toxins (carbon monoxide), and drugs of abuse.

**Management and Disposition**

Syncope is a common pediatric problem and usually has a benign, neurally mediated cause. Certain groups of patients may have an increased risk for cardiac syncope and should eventually be referred to a pediatric cardiologist for evaluation. These include athletes, patients with eating disorders or chronic fatigue, persons who use illicit substances, and survivors of congenital heart disease.\(^{116}\) The approach to management of patients with neurocardiogenic syncope is primarily one of education, involving avoidance of potential triggering events (hot, crowded environments; volume depletion) and recognition of the early signs and symptoms to allow timely maneuvers to abort the syncopal episode (e.g., assuming a supine position, ingesting fluids, leg crossing). The patient and the family must be reassured that these events are not life-threatening. A simple approach is to
encourage liberal fluid intake and to increase dietary salt intake. In a subgroup of patients with recurrent syncope or recurrent dizziness, however, a trial of an appropriate medication may be warranted. No large pediatric randomized studies have been conducted to investigate this application of such medications, which include beta-blockers, fludrocortisone, selective serotonin reuptake inhibitors, and alpha-agonists.115

KEY CONCEPTS

- Signs and symptoms of bacterial meningitis vary by age and can include nonspecific manifestations such as irritability and lethargy in infants and young children.
- A careful and detailed history is instrumental in determining whether or not an event was a seizure. If the event was a seizure, the history should delineate what type of seizure occurred (partial or generalized) and whether the clinical event fits into a known epilepsy syndrome.
- Status epilepticus constitutes a neurologic emergency that carries high morbidity and mortality rates. Usual initial treatment is with lorazepam followed by fosphenytoin or phenytoin.
- For patients experiencing a febrile seizure, ED management should include a review with family members of appropriate first aid, use of antipyretics, recurrence risk and risk for epilepsy, and follow-up care with the child’s primary care physician.
- The possibility of acute symptomatic, or provoked, seizures should always be considered, particularly because many of the causes of such seizures are treatable.
- A majority of headaches in children have nonserious causes that usually can be diagnosed by a careful history and physical examination.
- Radiologic evaluation using CT or MRI, or both, may be necessary to rule out secondary causes of headache such as intracranial hemorrhage, subarachnoid hemorrhage, brain abscess, or brain tumor.
- A toxicology screen is the test with the highest diagnostic yield for acute onset ataxia in children. The most common cause of benign positional vertigo in children is a migraine headache. Vertigo with hearing loss has a significantly different etiology than vertigo with no hearing loss.
- Most children with ataxia require hospitalization for evaluation and diagnosis.

Each year there are more than 11 million pediatric injury-related emergency department (ED) visits, 14.3% of which are due to fractures and dislocations. As a result of the physiologic and anatomic differences between children and adults, pediatric patients are susceptible to problems that do not affect the adult population. An understanding of these differences helps the emergency physician appropriately diagnose and treat musculoskeletal complaints in children. This chapter reviews the general principles and physiology of the pediatric musculoskeletal system, highlights the more common pediatric fractures, and describes musculoskeletal problems specific to the pediatric population.

**Anatomy and Physiology**

Several factors distinguish the pediatric musculoskeletal system from that of the adult. The most striking difference is the presence of a physis or growth plate. The physis is made up of proliferating cartilage cells between the metaphysis and epiphysis. Because it is composed of cartilage, the growth plate is the weakest part of the bone and is more likely to separate before the adjacent tendon or ligament tears. Accordingly, sprains are less frequent in the pediatric population than in the adult population, and physeal injuries are common.

Another factor that influences pediatric musculoskeletal injuries is the presence of a thick, physiologically active periosteum that is easily stripped from the bony cortex. When injuries occur, the periosteum often is torn on the convex side (i.e., the reverse aspect of a bone subjected to a deforming force) while remaining intact on the concave side (the aspect directly incurring the force of injury). In any case, the periosteum acts as a tether to reduce the amount of fracture displacement and, when it remains intact, aids in fracture reduction. The great bone-forming potential of the periosteum also facilitates the healing process: Callus formation is vigorous, and nonunion almost never occurs.

Growing bone is more porous, more pliable, and less dense than adult bone. These characteristics result in less strength, thus making children more susceptible to fractures. However, although it takes less force to cause deformation, pediatric bone is more likely to buckle when compressed or to bow when bent. Finally, because the bones are still growing, the potential for remodeling is greater with metaphyseal fractures. Growth can compensate for postreduction imperfections in both apposition and alignment, with deformities occurring in the plane of motion having the greatest potential for remodeling.

**Fracture Patterns**

As with fractures in adults, description of pediatric fractures includes the bony location (diaphysis, metaphysis, physis, or epiphysis), configuration, relationship of fracture fragments to one another (angulation and displacement), and relationship of fracture fragments to adjacent tissue (open or closed). The inherent differences between pediatric and adult bone result in fracture configurations that are not found in the adult population. Pediatric fractures can be classified as follows:

- **Plastic deformation**: Bone is bowed with no obvious cortical disruption.
- **Torus fracture** (buckle fracture): Buckling of bone without cortical disruption; it tends to occur because of compression failure of the bone at the metaphyseal-diaphyseal junction (Fig. 174-1). These fractures may be immobilized with a splint or cast or, if they involve the distal end of the radius, a Futura splint (Velcro wrist splint) or Prelude backslab. The Futura splint and Prelude backslab can be removed by the family or primary care provider in 3 to 4 weeks, thereby obviating the need for orthopedic follow-up. Buckle fractures also may be treated with a soft cast or a plaster splint.
- **Greenstick fracture**: Bone and one cortex are disrupted; the periosteum on the fracture’s compression side remains intact (Fig. 174-2).
- **Complete fracture**: The fracture propagates completely through the bone; included are transverse (Fig. 174-3), spiral (Fig. 174-4), oblique and comminuted (Fig. 174-5) fractures.

The presence of a relatively weak cartilaginous physis in growing bone makes physeal injury common in the skeletally immature. Although injuries to the physis can occur at any age, they are more common during rapid skeletal growth. The Salter-Harris classification system is the most frequently used tool to describe physeal injuries. This classification system is based on the extent of involvement of the physis, epiphysis, and joint (Table 174-1). Types I and II Salter-Harris injuries (Figs. 174-6 and 174-7) do not involve the germinal layer of...

the growth plate; therefore, the risk for growth arrest is small. In general, the higher the Salter-Harris classification, the greater the damage to the growth plate and the greater the likelihood of growth arrest or limb length abnormalities (Figs. 174-8 to 174-10 [Salter Harris III to V]). Type II fractures are the most common Salter-Harris injury and account for approximately three fourths of all growth plate injuries.

### SPECIFIC DISORDERS

#### Clavicle Fracture

The clavicle is one of the most frequently broken bones in children. The physis of the clavicle does not close until the age of 23 to 25 years and is at risk for injury until that time. Midshaft fractures account for approximately 85% of all clavi-
Fractures; distal and proximal fractures account for approximately 10% and 5%, respectively. The usual mechanism of injury is a fall on the shoulder or, less commonly, direct trauma to the bone itself. The child typically supports the affected side with the other hand and tilts the head toward the side of the fracture. Physical examination reveals point tenderness at the fracture site, with or without an obvious bony deformity. With a minimally displaced fracture, shoulder motion may be tolerated. Otherwise, range of motion of the shoulder is limited by pain. Although complications are rare, the proximity of the clavicle to the great vessels and brachial plexus calls for a thorough neurovascular evaluation; severe posterior dislocations can cause compression of the trachea, subclavian vessels, or brachial plexus. The proximity to the pleural cap also may result in pneumothorax.

An anteroposterior (AP) radiograph of the clavicle (Fig. 174-11) confirms the diagnosis. If clinical suspicion is high and the AP view does not reveal a fracture, a 30-degree cephalic view can be helpful. Specialized imaging studies are rarely needed, although computed tomography (CT) and duplex ultrasonography may be considered with proximal, posteriorly displaced fractures.

Clavicle fractures do not require anatomic reduction for healing or function; therefore, treatment is directed at maintaining comfort by splinting, ice, and analgesics. Distal clavicular fractures in adolescents, however, may require surgical management. Figure-of-eight splinting helps bring the clavicle out to length, relieves muscle spasm, and minimizes motion at the fracture site. Previously the treatment of choice, immobilization with the figure-of-eight splint has fallen out of favor with some physicians because of the risk for brachial plexus palsy with long-term use. Alternatively, a sling with or without a swath can be used to provide comfort by supporting the upper extremity and relieving the suspensory forces usually maintained by the clavicle. Most clavicle fractures heal without any problems, except for the development of bony callus at the fractures site; the younger the patient, the greater the potential for remodeling of this deformity. As the fracture stabilizes and the comfort level improves, range-of-motion exercises can be started, with gradual progression in intensity. Younger children generally require shorter periods of immobilization (2 to 4 weeks) than those used in adolescents and adults (4 to 8 weeks). Rehabilitation includes early range of motion and strengthening of the rotator cuff. Patients may return to contact sports when there is no tenderness at the fracture site or pain with ROM and they have achieved normal strength.

Although surgical intervention is uncommon with clavicle fractures, orthopedic consultation should be obtained if the fracture is open, if there is neurovascular compromise or associated rib cage fractures, or if there is greater than 100% displacement of the fracture fragment with severe skin tenting.

Clavicle fractures also can occur during childbirth and represent more than 90% of obstetric fractures. They occur equally in boys and in girls and on the right and on the left sides. Symptomatic neonatal clavicle fractures in the immediate postnatal period are characterized by “pseudoparalysis” of the affected arm; asymptomatic fractures may not be noticed until 10 days of age, when the bony callus becomes apparent. The diagnosis is made with radiographs.

Supracondylar Fractures of the Humerus

Supracondylar fracture is the most common elbow fracture in the pediatric population. Most such fractures are sustained in children younger than 8 years. Until that age, the tensile strength of the ligaments and joint capsule is greater than that of the bone itself; the weaker bone therefore yields to the stronger ligament complex around the joint.

Supracondylar fractures are classified as flexion or extension according to mechanism of injury. The extension type of fracture constitutes 95% of all supracondylar fractures and typically results from a hyperextension injury to the elbow incurred in a fall onto the outstretched arm. In this injury the olecranon is forcefully driven into the olecranon fossa, and the forces are concentrated in the supracondylar area. This mechanism results in failure of the anterior cortex and displacement of the distal fragment posteriorly in relation to the proximal fragment. With extension-type supracondylar fractures, the degree of displacement and continuity of the cortex are further defined by the Gartland classification (Table 174-2). In the less common flexion type of supracondylar fracture, the elbow is flexed when it hits the ground, and energy is transferred from the posterior aspect of the proximal end of the ulna to the distal end of the humerus. This mechanism results in a supracondylar fracture with anterior displacement of the distal fragment and failure of the cortex posteriorly.

Children with supracondylar humerus fractures may present with anything from mild swelling and elbow pain to a grossly displaced humerus. Gentle palpation is useful in determining the site of injury; however, manipulation should be avoided because movement may cause further neurovascular damage. Children with extension-type supracondylar fractures hold the affected arm in extension with an S-shaped configuration of the elbow and exhibit a prominence at the olecranon. Children with flexion-type supracondylar fractures hold the arm in flexion and exhibit an empty space where the olecranon should be. In all cases it is important to carefully assess distal neurovascular status. Motor and sensory function should be evaluated by assessing the radial, ulnar, and median nerves (Table 174-3). Two-point discrimination on the fingers provides a sensitive means of assessing sensory status: an abnor-

Figure 174-12. Ossification centers of the elbow: 1, capitellum; 2, radial head; 3, medial epicondyle; 4, trochlea; 5, lateral epicondyle. (From Connolly JF: DePalma’s Management of Fractures and Dislocations. Philadelphia, WB Saunders, 1981.)

Figure 174-13. Lateral radiograph demonstrating the bony relationships in a normal elbow. The anterior humeral line (solid) and proximal radial line (dashed) bisect the capitellum. (From Weissman BN, Sledge CB: Orthopedic Radiology. Philadelphia, WB Saunders, 1986.)

Bony relationships are helpful in evaluating a radiograph for the presence of a supracondylar fracture (Fig. 174-13). A true lateral view should demonstrate a figure-of-eight appearance of the distal humerus with bisection of the capitellum by the anterior humeral line. If the capitellum falls posterior to this line, an extension-type supracondylar fracture is likely. In all views, the proximal end of the radius and radial neck should point to the capitellum. Baumann’s angle also is helpful in diagnosing subtle supracondylar fractures.11 This angle is formed by a line drawn to follow the growth plate of the capitellum transected with a line that runs perpendicular to the axis of the humerus. The angle should be approximately 75 degrees. Baumann’s angle should be the same in both elbows, and differences between elbows can be used to detect subtle supracondylar fractures. Postreduction alterations in Baumann’s angle reliably predict the final carrying angle.12

Fat pads also provide a means for detecting occult supracondylar fractures. A lateral radiograph with the elbow flexed at 90 degrees may show an anterior fat pad protruding from the coronoid fossa. This finding is normal unless the pad is bulging.
or in the shape of a ship’s sail. This “sail sign” may indicate fluid in the joint, although alone it may not be a reliable predictor of a fracture. The posterior fat pad, however, sits snugly within the olecranon fossa and should never be seen unless there is a fracture around the elbow. In this case, blood pushes the fat pad laterally, thereby making it visible on a lateral radiograph of the elbow. Accordingly, visualization of a posterior fat pad suggests the presence of an occult fracture around the elbow. The presence of a posterior fat pad without an obvious fracture warrants obtaining oblique views of the elbow (Fig. 174-15), splinting, and follow-up.

Plain radiographs usually are sufficient for diagnosing supracondylar fractures; however, if the diagnosis remains in question after AP, lateral, and oblique radiographs are obtained, ultrasound imaging may be useful in infants, and magnetic resonance imaging (MRI) may be useful in older children. With strong clinical suspicion, some orthopedic surgeons bypass MRI in favor of an intraoperative arthrogram.

ED treatment of supracondylar humeral fractures is determined by displacement and neurovascular status. A pale, pulseless cold hand mandates emergency consultation with an orthopedic surgeon. If an orthopedic surgeon is unavailable and the vascular supply has not been restored, reduction should be attempted (Fig. 174-16). If necessary, reduction can be performed by a single operator. With the patient supine, the shoulder held in 90 degrees of forward flexion, and the elbow slightly flexed, both hands are placed on the arm proximal to the fracture and both thumbs are placed on the posterior aspect of the fracture fragment. Then, while the thumbs are directed distally, the fragment is lifted onto the distal metaphysis. The return of blood supply is marked by the hand becoming warm and pink. If perfusion does not improve, another reduction may be attempted, with care taken to not entrap the brachial artery and median nerve. Multiple attempts at reduction increase the likelihood of neurovascular injury and swelling; therefore, no more than two reductions should be attempted. A supracondylar fracture with a pulseless hand that is warm and pink does not need to be reduced and should be splinted as it lies so that vascular status is not further compromised. The elbow should be splinted in relative extension, because too much flexion in conjunction with swelling may obstruct the brachial artery and contribute to limb ischemia.

Gartland type I fractures can be splinted in the ED with the arm maintained in 90 degrees of flexion and neutral rotation. Hospital admission is not required, but referral to an orthopedic surgeon the next day is recommended. Gartland type III fractures require immediate orthopedic consultation and should be treated by either closed reduction and percutaneous pinning or open reduction and internal fixation in the operating room. Treatment of a partly displaced type II fracture is controversial. Some surgeons reduce and pin it in the operating room, whereas others perform closed reduction and keep the arm immobilized in a cast. Treatment of displaced supracondylar fractures by closed reduction and casting is associated with higher complication rates than is treatment by closed reduction and pinning; therefore, most such fractures are treated with pinning and casting for 3 to 4 weeks.

The primary complications of supracondylar fractures are related to neurovascular injury. Type III fractures are at greatest risk, with neurovascular compromise occurring in as many as 49% of patients. The median nerve is involved in half of the cases and is associated with posterolateral displacement. The radial nerve is involved in almost one third of patients and is associated with posteromedial displacement. Brachial artery injuries, including arterial entrapment, laceration, intimal tears, or compression from compartment syndrome, occur in approximately 40% of patients and are found with either type of displacement. Fortunately, the brachial artery has many branches around the elbow, and flow to the forearm and hand can be maintained even when the brachial artery is injured.

Despite the frequency of neurovascular deficits immediately after the accident, most nerve palsies are caused by stretching or contusion and resolve spontaneously. The typical course for nerve injuries is complete resolution. Although motor function usually returns within 12 weeks, sensory function may not return for 6 months or longer. If clinical or electromyographic evidence of nerve recovery is lacking after 5 months, exploration and neurolysis are indicated. Volkmann’s ischemic contracture (contracture deformity of the fingers, hand, and wrist) and permanent limb disability are the end result of untreated vascular injury. This complication is extremely rare and easily prevented by close observation and evaluation for the development of compartment syndrome. A few supracondylar fractures heal with a “gunstock” deformity; however, the combination of varus, hyperextension, and medial rotation of the limb is not a functional problem and, except in severe cases, requires no treatment. Severe cases can be corrected by humeral osteotomy.
Monteggia Fracture-Dislocation

Monteggia fracture-dislocations are characterized by a fracture of the proximal third of the ulna plus dislocation of the radial head. The radiographic evidence can be very subtle, with only a minor greenstick fracture or bowing of the ulna. Isolated ulna fractures are rare in children; therefore, with all such fractures, AP and lateral radiographs of the elbow should be obtained to rule out dislocation of the radial head. The radial head should align with the capitellum on all radiographs of the elbow; if it does not, then a Monteggia injury should be suspected. (A radiograph showing a classic Monteggia injury can be found online at http://www.hawaii.edu/medicine/pediatrics/pemxray/v1e15.html.)

Monteggia fracture-dislocations require urgent referral to an orthopedic surgeon for closed reduction of the radial head dislocation and repair of the ulna fracture. Complications include permanent radial head dislocation, valgus deformity of the arm, loss of pronation, and late radial nerve palsy.
Nursemaid’s Elbow

In one study, radial head subluxation, or nursemaid’s elbow, was the most common upper extremity injury in children younger than 6 years presenting to a pediatric ED.19 It typically occurs when axial traction is placed on an extended and pronated arm, as when the child is pulled up or swung by the arms. It also may occur when the child falls onto the outstretched arm, sustains minor direct trauma to the elbow, or simply twists the arm. In infants, radial head subluxation can occur when an extended arm is caught beneath the infant’s body while being rolled over. In pathoanatomic terms, subluxation occurs when the annular ligament becomes loosened from the head of the radius and slips into the radiocapitellar joint, where it becomes entrapped (Fig. 174-17).

Nursemaid’s elbow occurs in children a few months to 5 years of age and has a peak incidence between 2 and 3 years of age.20 It has been reported in children younger than 6 months20 and has been seen in children as old as 9 years. This injury has a slight predilection for girls.

The history often includes an event involving a mechanism consistent with the injury followed by acute onset of arm pain that may or may not be localized to the elbow. The affected arm is held against the body, with the elbow slightly flexed and the arm pronated. Physical examination is significant for lack of swelling, erythema, ecchymosis, or deformity. Examination may reveal mild tenderness to palpation of the radial head. Pain is elicited with supination, pronation, and elbow flexion.

The diagnosis of nursemaid’s elbow is made clinically, and radiographs are not necessary. If, however, significant point tenderness, swelling, or ecchymosis is present or if the history suggests another injury, such as a supracondylar fracture, radiographs should be obtained. Although not commonly used as a diagnostic procedure, ultrasound imaging may demonstrate a widened space between the radial head and the capitellum.21

Radial head subluxation is an orthopedic injury that is easily reduced without sequelae. Classically, the affected elbow is gripped with the clinician’s thumb over the radial head, and with the other hand, the clinician flexes and supinates the patient’s arm. As the radial head relocates, the clinician feels it click or “clunk” under the thumb. Hyperpronation of the forearm also is effective in reducing radial head subluxation. As is done in the flexion-supination maneuver, the child’s affected elbow is held with the clinician’s thumb over the radial head, but then flexion-supination is replaced with hyperpronation of the forearm. Success rates range from 80%22 to 92%22 with supination and from 93%23 to 98%24 with pronation. Pronation also may be less painful to the patient24,25 and is the reduction method of choice.24 After successful reduction, the child typically uses the arm normally within 10 minutes. This may be delayed in younger children and when the injury occurred more than 4 to 6 hours before reduction. Neither splinting nor orthopedic referral is required after a successful reduction.

Failure to reduce the subluxation of nursemaid’s elbow may result from improper reduction technique; swelling of the annular ligament as a result of edema, hemorrhage, or hematoma; or disruption of the annular ligament. Persistence of the subluxation also is more likely if reduction is attempted 12 hours or longer after the injury.

If two attempts at reduction fail to restore normal use of the arm, alternative diagnoses should be entertained. Because of the similarity in clinical findings, children also should be assessed for fractures of the clavicle and elbow. If no other pathologic process is found and the child is still not using the arm, a posterior splint should be applied with the elbow kept at 90 degrees and the forearm in supination. Follow-up evaluation with an orthopedic surgeon should be arranged for the next day.

Parents should be cautioned to avoid traction on the forearm and elbow, because recurrence rates of radial head subluxation range from 5 to 39%, depending on the referral population studied.20,22,24 With recurrent subluxations, immobilization in a posterior splint with the elbow maintained at 90 degrees and the forearm supinated may be warranted. The need for open reduction or repair of the annular ligament is exceedingly rare.

Toddler’s Fracture

Toddler’s fractures are oblique nondisplaced fractures caused by low-energy torsional forces applied to the very porous bone of infants and young children. Previously, it referred only to tibial fractures in children between 9 and 36 months of age, but the term is now applied more loosely. The mechanism of injury can be as mild as the child’s twisting on the leg while walking or a fall from an insignificant height. In some instances, the mechanism of injury may be unknown. The child will exhibit a limp or may refuse to walk on the affected leg. Some

---

Figure 174-17. Nursemaid’s elbow. In a nursemaid’s elbow injury, as an axial force is applied, the annular ligament around the radial head is dislodged. The ligament is then partially dislocated into the radiocapitellar joint when the arm is released. (From Simon R, Kownigsknecht S: Emergency Orthopaedics: The Extremities, 2nd ed, E Norwalk, Conn, Appleton & Lange, 1987.)
children will revert to crawling and can crawl without pain. Examination may show mild swelling of the leg and point tenderness. Gentle twisting of the lower part of the leg may elicit pain.

AP and lateral radiographs may reveal a spiral or oblique fracture extending downward and medially through the distal third of the tibia (Fig. 174-18). An internal oblique radiograph is helpful if evidence of fracture is absent on the AP or lateral view. If findings on all views are negative, consideration should be given to fractures elsewhere in the limb. If no fracture is apparent, the child should be splinted for comfort and radiographs repeated in 10 days, at which time periosteal new bone or sclerosis of the fracture edges will make the fracture visible. If findings on these radiographs are negative and the child is still limping, further evaluation should be undertaken to rule out osteomyelitis and malignancy. Bone scans often are helpful in assessing a limping toddler and are more sensitive than plain radiographs for detection of fractures. Treatment of a toddler’s fracture consists of use of a below-knee walking cast for approximately 3 weeks.

The presence of a spiral fracture without an appropriate history may raise concern for nonaccidental injury (i.e., child abuse). Midshaft fractures, which are more common in abused children, and tibial fractures in nonambulating children, as well as other unexplained or frequent injuries, should prompt further evaluation.

**Skeletal Aspects of Nonaccidental Injury**

**Perspective.** Fractures are the second most common manifestation of child abuse, second only to soft tissue injury, and are present in up to 70% of physically abused children. Fractures associated with child abuse occur in the very young: 50% in children younger than 12 months and 94% in children younger than 3 years. With child abuse, a timely and accurate diagnosis is imperative, because children who are returned to an abusive home face a 35% chance of repeated abuse and a 10% chance of death.

No fracture is pathognomonic for abuse, but certain fracture patterns are more worrisome than others. Any fracture in a child younger than 1 year, fractures at different stages of healing, and bilateral or multiple fractures indicate a need for thorough assessment for intentional (nonaccidental) injury. Injuries that are especially concerning include complex skull fractures, rib fractures, metaphyseal fractures, and vertebral fractures or subluxations. Midshaft humeral and scapular fractures are nearly always associated with abuse, as are approximately 70% of femoral fractures in children younger than 1 year.

**Specific Disorders and Injuries**

**Diaphyseal Fractures**

Although multiple fractures at different stages of healing are strongly suggestive of child abuse, the most common manifestation of child abuse is an isolated diaphyseal fracture, which occurs four times as often as classic metaphyseal fractures. The humerus, femur, and tibia are the most frequently fractured long bones; the radius and ulna are the most infrequently fractured. With the exception of supracondylar fractures, all fractures of the humerus in children younger than 3 years are strongly suggestive of abuse.

**Metaphyseal Fractures**

Although less common than diaphyseal fractures, metaphyseal fractures are more specific for child abuse. Metaphyseal fractures most commonly affect the tibia, femur, and proximal end of the humerus. Corner fractures and bucket handle fractures, which may be the same fracture viewed in two different projections, result from violent shaking or forceful pulling or twisting of an infant’s limb. The diagnosis is made by careful evaluation of high-quality plain radiographs. The tight adherence of the periosteum at the metaphysis precludes an active periosteal response, making these fractures difficult to diagnose even in the healing stages. Additionally, after healing these fractures may not be visible due to rapid bone remodeling. Bone scans, although sometimes helpful, are difficult to interpret because of the normally increased radionuclide uptake in the metaphyseal area.

**Rib Fractures**

Rib fractures are present in 5 to 27% of cases of child abuse, with 90% of such fractures occurring in children younger than 2 years. The young pediatric rib cage is very compliant, and considerable force is required to break a rib. Accordingly, rib fractures are seldom seen in unintentional injury and are almost never seen after cardiopulmonary resuscitation. When present, post-resuscitation rib fractures are anterior and also may be multiple. In a child younger than 3 years, the positive predictive value of a rib fracture as an indicator of intentional trauma approaches 100%.

With nonaccidental injury, posterior rib fractures are most common and result from maximal mechanical stress as the rib is levered over the transverse process of the vertebral body when infants are grasped and shaken. The ribs fail mechanically at the head or neck. Abuse-related rib fractures tend to be multiple and symmetrical and may be difficult to diagnose acutely on standard radiographs. Repeating the radiographic exam at 7 to 10 days after the injury is advised if findings on the initial films are negative but the level of clinical suspicion is high. Radiographic findings include callus formation or widening of the rib neck as a result of apposition of new bone subperiosteally. Bone scans can be helpful in detecting fractures in the acute setting.
Skull Fractures

Skull fractures are the second most frequent orthopedic injury in abuse and occur more commonly in abuse cases than from unintentional trauma. Eighty percent occur in infants younger than 1 year, and although complex skull fractures are more suspicious for abuse, linear skull fractures are the most common type. Standard skull radiographs may not be adequate for diagnosis and are reported to miss more than 25% of head injuries. Children who meet high-risk criteria (the presence of rib fractures, multiple fractures or facial injury, or age younger than 6 months) should undergo CT or MRI to assess for occult head injury.

Periosteal New Bone Formation

Periosteal new bone formation, which is one of the most common findings in cases of abuse, reflects separation of the periosteum from the bone and may be the only manifestation of orthopedic trauma related to child abuse. It may be present with or without a fracture. It results from shaking, from acceleration-deceleration forces applied to an unsupported limb, or from forceful gripping.

Diagnostic Strategies: Radiology. Conventional skeletal radiography is the screening examination of choice in cases of suspected physical abuse. Unsuspected fractures are found in 22% of physically abused children and are more common in the very young. A complete skeletal survey is recommended for all physically abused children younger than 2 years and for all infants younger than 1 year with evidence of abuse or neglect. Complete skeletal surveys are rarely indicated in children older than 5 years; in children between 2 and 5 years of age, the need for a skeletal survey is determined on a case-by-case basis. A skeletal survey consists of an AP view of the extremities (including the hands and feet), frontal and lateral views of the thoracolumbar spine (including the ribs), and an AP and lateral skull series. In cases in which abuse is strongly suspected but radiographic findings are negative, bone scanning serves as an adjunct and is complementary to the skeletal survey in detecting injury. It is sensitive for detection of subtle rib, spine, and diaphyseal trauma, especially in the acute setting, but because the radiographic abnormalities can persist for years, it is not reliable in determining the age of the fracture.

Differential Considerations. Although most cases of intentional injury are easily diagnosed with a thorough history and physical examination, certain conditions can be confused with child abuse. Metaphyseal cupping and spurting and periosteal new bone formation are two normal variants that radiographically are almost identical to the findings in cases of child abuse. These features are seen in more than 40% of normal infants. They appear between 2 and 3 months of age and may persist until 8 months of age. These findings can be differentiated from child abuse by subtle radiographic clues: normal-variant infantile metaphyseal spurs are in continuity with normal bone and cortex, and physiologic periostitis is bilateral, confined to the diaphysis, and smooth and lamellar in appearance. Physiologic periostitis also tends to be more obvious on the medial aspect of the bone and most commonly involves the femur, although it also is seen in the humerus and tibia. Radiographic differentiation between normal variants and trauma-related injury is extremely difficult, and the clinical findings must be taken into account.

Osteogenesis imperfecta (OI), a heritable disorder of connective tissue, is an alternative cause of multiple fractures with minimal trauma. In the United States, the estimated incidence is 1 in 20,000 persons. This estimate includes cases in children in whom the condition is diagnosed within 1 year of birth but does not include milder forms of the disease that are not diagnosed until later in life. Accordingly, the true incidence of OI may be significantly higher. Most types of OI have been linked to mutations in type I collagen genes that interfere with either the synthesis or the construction of collagen subunits. Clinical features include bone fragility, ligament laxity, defective dentinogenesis, short stature, scoliosis, middle ear deafness, blue sclera and tympanic membranes, and misshapen skull. On radiographs, the bones are diffusely osteopenic, with thin cortices and attenuated trabecular patterns. The long bones have narrow diaphyses, and bowing and fractures are common (Fig. 174-19).

Four types of OI are recognized, with clinical presentations ranging from intrauterine demise to occurrence of multiple fractures in an infant to almost complete absence of symptoms in an adult (Table 174-5). The diagnosis of OI is made on the basis of the history, physical examination, and radiographic findings. Confirmation is by skin biopsy and culture of dermal fibroblasts for evaluation of type I collagen. However, because the molecular basis for the entire spectrum of disease has not been established, up to 10% of cases of OI would be missed with skin biopsy alone. ED management of children with OI includes appropriate orthopedic referral for fractures and primary care referral for hearing evaluation.

In addition to musculoskeletal complaints, children with OI are predisposed to abdominal pain and neurologic abnormalities. The abdominal pain is thought to be related to the trefoil-shaped pelvis and acetabular protrusion associated with OI. These structural abnormalities narrow the pelvic outlet, resulting in partial rectosigmoid obstruction and subsequent constipation or obstipation. Neurologic abnormalities associated with OI result from basilar impression. Basilar impression, or elevation of the floor of the posterior cranial fossa, is reported to occur in 25% of patients with OI. It is seen most frequently in children with OI type IVB (71%), and one half of the patients with this type of OI will have neurologic signs or symptoms of compression of the posterior fossa structures.
The signs (nystagmus, facial spasm, nerve paresis, pyramidal signs, and papilledema) may predate the symptoms (headache, neuralgia, imbalance, weakness, and incontinence). The most serious outcomes with basilar impression include brainstem compression, respiratory arrest, and sudden death. Any neurologic changes in a patient with OM1 mandate neurosurgical evaluation.

Several metabolic abnormalities can be associated with frequent fractures and radiographic abnormalities. Rickets, which results from vitamin D or calcium deficiency or hyperparathyroidism, can be manifested by diffuse osteopenia, fraying of the metaphysis, fractures, periosteal new bone formation, widening of the physis, and well-defined transverse stress fractures in the shafts of long bones. The diagnosis can be confirmed with laboratory testing. Menkes’ kinky hair syndrome, a rare disorder of X-linked recessive inheritance involving inadequate copper absorption, is characterized by wormian (intersutural) skull bones, osteopenia, and metaphyseal fractures and spurring. Affected children have sparse, kinky hair with abnormal dentition and exhibit developmental delay. Serum levels of copper and ceruloplasmin are low and confirm the diagnosis. Hypervitaminosis A, although a rare cause of fractures, results in a thick periosteal reaction of tubular bones, most frequently the ulna and metatarsals, and widening of the cranial sutures. The epiphyses and metaphyses are normal. The diagnosis is based on the history and vitamin A levels.

Congenital syphilis also can mimic nonaccidental injury. Skeletal findings in congenital syphilis frequently are diffuse and symmetrical and involve the long bones, skull, and small bones of the hands and feet. Radiographic findings include osteolytic defects, periosteal reaction, and metaphyseal lucencies parallel to the physis. The diagnosis is confirmed by serologic testing.

The epiphyses and metaphyses are normal. The diagnosis is based on the history and vitamin A levels.

Congenital syphilis also can mimic nonaccidental injury. Skeletal findings in congenital syphilis frequently are diffuse and symmetrical and involve the long bones, skull, and small bones of the hands and feet. Radiographic findings include osteolytic defects, periosteal reaction, and metaphyseal lucencies parallel to the physis. The diagnosis is confirmed by serologic testing.

### Developmental Dysplasia of the Hip

**Perspective.** Developmental dysplasia of the hip (DDH), formerly known as “congenital dislocation of the hip,” is abnormal formation of the hip joint that occurs between organogenesis and fetal maturity. It encompasses a spectrum of disease ranging from “subluxatable” (“loose”) hips to frank dislocation of the hips.

In white neonates, the incidence of dysplasia is 1%, and the incidence of dislocated hips is 0.1%. DDH is more common in Native American populations and less common in African American, Korean, and Chinese populations. An apparent familial predisposition for the development of DDH has been reported; one British study noted that more than 20% of children who required treatment for DDH had a positive family history. DDH is more common in girls and most frequently is unilateral (80%). With unilateral involvement, a predilection for the left side is characteristic. Associated birth factors include oligohydramnios, breech presentation, torticollis, talipes equinovarus, metatarsus adductus, and firstborn status. Postnatally, swaddling infants with their hips and knees in extension predisposes to dislocation.

**Principles of Disease.** The etiology of DDH is not entirely clear. Three theories have been postulated: mechanical issues related to fetal position and environment, primary acetabular dysplasia, and ligamentous laxity which is enhanced by maternal relaxin hormone. Each theory has merit, and a combination of factors that contribute to the development of DDH is most likely.

**Clinical Features.** DDH may be diagnosed at birth, or despite frequent and appropriate physical examinations, it may not be discovered until later in life. In one study, 6% of children with documented DDH had normal findings on physical examination at birth. Conversely, in more than 50% of infants found to have unstable hips at birth, spontaneous stabilization occurs within 3.5 days.

The clinical manifestations of and physical examination findings with DDH are as diverse as the disease itself. This variability is due to differences in the severity of the dysplasia and the progressive changes that occur over time. Up to 4 to 6 months of age, the diagnosis of DDH is based on physical examination findings of leg length, skinfold, and range-of-motion asymmetry and abnormal findings on the Barlow provocative test and the Ortolani reduction maneuver. Skinfold asymmetry (Fig. 174-20) can be noted in the groin, below the buttock, and along the thighs. Although skinfold asymmetry is not specific for DDH, being present in approximately 30% of infants with normal hips, it is sensitive, and the diagnosis of DDH is very unlikely in infants with normal skinfold symmetry. Range of hip motion also is helpful in diagnosing DDH; any asymmetry in hip flexion, abduction, and external rotation should prompt further investigation. Although the general physical examination can be helpful in assessing hip stability, the physical diagnostic cornerstones for diagnosing DDH in young infants are the Ortolani reduction maneuver and the Barlow provocative test. The Ortolani reduction maneuver is performed in an attempt to reduce a dislocated hip back into normal position, and the Barlow provocative test detects a
subluxatable or dislocatable hip (Box 174-1). Abnormal findings include the presence of a “clunk” with the Ortolani test and any abnormal movement between the femoral head and the acetabulum with the Barlow maneuver.

After approximately 4 to 6 months of age, soft tissue contractures develop, the Ortolani and Barlow tests yield less information in detecting unstable hips, and range-of-motion abnormalities become more apparent. Parents may notice limited or asymmetrical leg movements or difficulty with diapering. Findings on examination include limited abduction (Fig. 174-21), relative shortening of the ipsilateral femur (Galeazzi’s sign) (Fig. 174-22), and skinfold asymmetry. In children with bilateral DDH, the diagnosis is even more difficult beyond the first few months of life because of the absence of asymmetry. After the development of contractures, physical findings in bilateral DDH include widening of the perineum, abduction less than 60 degrees, and the appearance of abnormally short thigh segments.

With the onset of walking, gait asymmetry or asymmetrical in-toeing or out-toeing is a clue to the presence of DDH. Adduction and flexion contractures, a Galeazzi sign, hyperlordosis, and a waddling gait are common features. Clinical observation of the appropriate maneuver reveals a Trendelenburg sign: While standing, the patient lifts one leg up at a time, and because the gluteal muscles are weakened on the affected side, the pelvis drops to the opposite side. With bilateral DDH, children have a wide-based waddling gait.

**Diagnostic Strategies.** Radiographs of infant hips are extremely difficult to interpret and may provide a false sense of security if the findings seem normal. Before the child is 3 to 6 months old, at which time the femoral head ossifies, an abnormal relationship between the upper end of the femur and the acetabulum may not be apparent. Additionally, in infants with unstable but nondislocated hips, radiographs will show the hip in position, so its instability goes undetected. Before femoral head ossification, a better diagnostic test is ultrasonography. Because a large percentage of infants will have abnormal ultrasound findings in the first week of life, with many of these abnormalities resolving within a few weeks, it is best to delay ultrasound imaging in children with nondislocated but possi-
bly unstable hips until 4 to 6 weeks of age. Children with dislocated hips require immediate ultrasound examination. Plain radiographs are useful after the age of approximately 6 months. A standard AP radiographic view of the pelvis with both legs extended in neutral abduction is then sufficient for diagnosis. Radiographic findings may include displacement of Shenton’s line (a curvilinear line defined by the medial border of the femoral neck and the superior border of the obturator foramen) and a widened acetabular angle; angles greater than 30 degrees are abnormal, and those greater than 40 degrees indicate dislocation (Fig. 174-23).

Management. Treatment of DDH is most successful when begun early, and delay in detection can be associated with a significantly worse outcome. Patients with untreated abnormalities of the hips that persist beyond the newborn period are at risk for osteoarthritis, pain, abnormal gait, leg length discrepancy, and decreased agility. For this reason, all children who are seen in the ED should have their hips examined until they are able to walk. Neonates who have a dislocated hip at birth should be referred to a pediatric orthopedist immediately. When a newborn has a loose but nondislocated hip, referral can be made within 2 weeks. Children with loose hips who are seen after the newborn period should be referred to a pediatric orthopedic surgeon immediately.

The essential basic goal of treatment is concentric reduction of the hip. After concentric reduction, stability must be obtained so that when the leg is allowed to move, it does not subluxate or dislocate. This position is maintained until all of the dysplastic features of the bone and cartilage have resolved. The two most important complications are failure to achieve these goals and aseptic necrosis of the femoral head.

In the first 6 months of life, use of the Pavlik harness is the mainstay of treatment. It is a dynamic splint that allows movement while preventing hip extension or adduction. Other treatment options include application of the Craig and von Rosen splints. If these modalities are unsuccessful, application of a hip spica cast usually is the next choice. Beyond 6 months of age, use of a hip spica cast or fixed orthosis is required. Surgical release of contracted muscles may be necessary in older infants and children, and open surgical reduction is required if complete closed reduction is not achieved. Femoral or pelvic osteotomy (or both) may be necessary to reduce and stabilize dislocated hips in children older than 18 months. Beyond the age of 4 years in bilateral cases and 8 years in unilateral cases, reduction should not be attempted. The risk of aseptic necrosis and the potential for a poor result are too high.

Hip Pain in Children

Perspective. Hip pain in children is an extensive topic with myriad causes (Box 174-2). The extensive differential diagnosis precludes an in-depth review of the topic in this chapter, but an overview of some of the more common causes of hip pain in children is presented next.
Specific Disorders/Injuries

Transient Synovitis

Transient synovitis is the most common cause of hip pain in childhood. It is a self-limited condition caused by a nonpyogenic inflammatory response of the synovium. Although it has been reported in children as young as 3 months and occasionally occurs in adults, its peak incidence is between 3 and 6 years of age. Transient synovitis of the hip affects boys more commonly than girls and has a slight predilection for the right side. Less than 5% of cases are bilateral. Approximately 75% of cases occur in the first 3 days of the onset of symptoms, whereas the other half occur acutely, usually within the first 3 days of the onset of symptoms. Transient synovitis affects boys more commonly than girls and has a slight predilection for the right side. Although most commonly affecting the hip, transient synovitis also can affect the knee.

The etiology of transient synovitis is unknown. Current theories imply an association with active or recent infection, trauma, or allergic hypersensitivity. At least one half of the children with transient synovitis have or recently have had an upper respiratory illness. One study demonstrated a fourfold rise in viral titer in 45% of patients and elevated serum interferon levels, consistent with a concurrent viral infection, in 43% of patients with transient synovitis. Trauma commonly is associated with transient synovitis, but no clear relationship has been demonstrated. Similarly, a causal association with an allergic reaction to an infectious agent has been suggested but not proved.

It is estimated that transient synovitis of the hip may occur in up to 3% of children. Hip or groin pain is the most common initial finding, but referred pain to the medial aspect of the thigh or knee is found in 10 to 30% of patients. Affected patients either walk with a limp or, with severe pain, refuse to walk at all. The leg is held in flexion with slight abduction and external rotation. On examination, passive movement usually is pain-free; however, pain and a slightly decreased range of motion may be noted with extreme internal rotation or abduction. Although most children with transient synovitis tend to otherwise be well, some will have a low-grade fever and malaise.

The diagnosis of transient synovitis is one of exclusion and relies on the history and physical examination in combination with limited laboratory testing and AP and “frog-leg” lateral radiographs of the pelvis. Laboratory tests are used to help distinguish children with transient synovitis from those with septic arthritis. In transient synovitis, laboratory values may be normal or may reveal mild elevations in the white blood cell count and erythrocyte sedimentation rate (ESR), both consistent with a nonspecific inflammatory process. Multiple studies have attempted to define criteria to help differentiate transient synovitis from septic arthritis. Clinical decision rules have included the presence or absence of fever, the ability to bear weight, white blood cell counts, the inflammatory markers ESR and C-reactive protein (CRP), side-to-side differences in the width of the joint space on radiographs, and previous visits to a health care provider for related symptoms. Kocher and colleagues found four independent multivariate predictors of septic arthritis: fever, inability to bear weight, ESR of 40 mm/hour or higher, and a serum white blood cell count greater than 12,000 cells/µL. Patients with three of the four predictors had a 93% chance of having septic arthritis, and those with all four had a 99% likelihood of pyarthrosis. A subsequent study to validate these findings showed that patients with none of the predictors had a 2% probability of septic arthritis; those with one of four criteria had a 9.5% probability; with two of four, a 35% probability; with three of four, a 73% probability; and with all four predictors, a 93% probability of septic arthritis. When this algorithm was tested at another institution, however, the presence of all four Kocher criteria predicted septic arthritis only 59% of the time. In general, children with transient synovitis and septic arthritis, the overlap of laboratory values and historical features is too great to provide a foolproof diagnostic algorithm.

Although radiographs of the hip and pelvis tend to be normal in appearance with transient synovitis, they are helpful in excluding other diseases. Radiographic findings consistent with transient synovitis include mediolateral joint space widening, an accentuated pericapsular shadow, and Waldenström’s sign, which is lateral displacement of the femoral epiphysis with surface flattening secondary to effusion. However, these findings also are apparent in Legg-Calvé-Perthes disease and, if present, mandate close follow-up or further investigation with MRI. If joint aspiration is necessary to clarify the diagnosis, ultrasonography can be used to guide hip joint aspiration. Effusions are present in 60 to 70% of cases of transient synovitis; however, they also are present with septic arthritis, osteomyelitis, acute slipped capital femoral epiphysis (SCFE), Legg-Calvé-Perthes disease, rheumatoid and infectious arthritis, malignancy, and osteoid osteoma. Accordingly, the presence of an effusion on ultrasonography cannot be used to distinguish transient synovitis from other causes of hip pain.

Nuclear scintigraphy in patients with transient synovitis is helpful in differentiating transient synovitis from osteomyelitis (with or without septic arthritis), Legg-Calvé-Perthes disease, and SCFE. Scintigraphy may demonstrate differential uptake in the capital femoral epiphysis, with decreased uptake early in the course of the disease and increased uptake later on. The early changes also are seen with very early Legg-Calvé-Perthes disease and suggest that some children with transient synovitis experience ischemia of the capital femoral epiphyses. This ischemia may be caused by an intracapsular effusion that tamponades vessels along the femoral neck. These ischemic findings have not yet been shown to have clinical significance.

Most cases of transient synovitis can be managed at home with close follow-up by the child’s primary care provider. Generally, these children have a mild limp and, if treated with nonsteroidal anti-inflammatory drugs, often show clinical improvement with relief of symptoms. A complete blood count and determination of ESR should be performed, and radiographs should be obtained. Patients with severe symptoms, fever, and an elevated ESR should be evaluated for septic arthritis. If there is any doubt about the diagnosis, immediate orthopedic consultation is necessary.

Treatment of transient synovitis is twofold: (1) rest of the affected joint achieved with non-weightbearing or, in cases associated with extreme pain, bedrest and (2) reduction of the inflammatory process with anti-inflammatory medications. Temperatures should be monitored closely, and any fever should be reported to the physician. Children are allowed a gradual return to activity as the pain subsides, and full unrestricted activity is permitted when the hip is completely pain-free with no evidence of a limp. Although many children with transient synovitis have an effusion, aspiration of the joint is not routinely performed, and there is no strong evidence that aspiration shortens the clinical course or prevents osteonecrosis. Repeat examination is recommended for all children within 12 to 24 hours and then again after 10 to 14 days if the symptoms have not resolved.

The prognosis for children with transient synovitis is excellent. Up to 75% of patients have complete resolution of pain within 2 weeks and 88% within 4 weeks. The remainder may...
have less intense but persistent pain for up to 8 weeks. Relapse is possible, although infrequent, and usually occurs within 6 months. In general, long-term sequelae of transient synovitis are infrequent; these may include asymptomatic coxa magna (enlargement and deformity of the femoral head and neck caused by hypertrophy of cartilage secondary to inflammation) and mild degenerative cystic changes of the femoral neck. These changes persist for years and may be accompanied by radiographic degenerative change, but they do not tend to cause long-term functional disability. Additionally, a small number (2%) of cases of transient synovitis follow a clinical and radiographic course consistent with Legg-Calvé-Perthes disease. Whether this is due to ischemia of the capital femoral epiphyses during the early stages of synovitis or reflects an initial misdiagnosis is unclear. It is recommended that children with persistent symptoms undergo ultrasonography to evaluate for the presence of an effusion. Persistent joint effusion beyond 4 to 6 weeks may be associated with the subsequent development of Legg-Calvé-Perthes disease.50 Some experts recommend routine 6-month follow-up radiographs for all children with transient synovitis,43 whereas others reserve radiographs for children who remain symptomatic.51

Acute Septic Arthritis

Septic arthritis refers to microbial invasion and infection of the joint space. Bacterial pathogens are common in patients with acute septic arthritis, whereas fungal and mycobacterial pathogens tend to be associated with a more indolent septic arthritis. Acute septic arthritis occurs in all age groups but is more common in children: 70% of cases occur in children younger than 4 years, and the peak incidence is between 6 and 24 months. Boys are affected twice as frequently as girls. Predisposing factors include preceding viral infection, trauma, immunodeficiency, hemoglobinopathy, hemophilia with recurrent hemarthroses, diabetes, intravenous drug abuse, rheumatoid arthritis, and intra-articular injections or operations. In 75% of cases of septic arthritis, the pathologic process involves the joints of the lower extremity, with the knee being most commonly and the hip second most commonly involved. Other affected joints, in order of involvement, include the ankle, elbow, shoulder, and wrist. More than 90% of the cases are monoarticular.

Hematogenous seeding, local spread, or traumatic or surgical infection may cause septic arthritis. In children, it most commonly results from hematogenous spread as bacteria pass into the synovial space through the highly vascular synovial membrane. The synovial membrane lacks a limiting basement membrane, which facilitates bacterial translocation. The bacteria then bind to bone and cartilage, initiating an inflammatory response that breaks down the joint by two mechanisms: directly through the effects of proteolytic enzymes and indirectly through pressure necrosis caused by accumulation of purulent synovial fluid.

Contiguous spread of infection from osteomyelitis to the joint space occurs in approximately 10% of cases and is more common in newborns and young infants. In these children, blood vessels cross the physis, thereby connecting the metaphysis and epiphysis and allowing bacteria direct access into the joint space. Additionally, the joint capsules of the hip and shoulder overlie the bony metaphyses of the femur and humerus, facilitating direct extension of osteomyelitis into these joint spaces.

The most common bacterial causes of septic arthritis are listed in Table 174-6. In all age groups, Staphylococcus aureus is the most common cause of septic arthritis and infection, with community-acquired MRSA becoming more common.22 In addition to the organisms listed in Table 174-6, additional causative organisms include Neisseria gonorrhoeae in neonates and sexually active adolescents, Pseudomonas aeruginosa and Candida species in intravenous drug abusers, Salmonella species in children with sickle cell disease, and gram-negative bacteria in immunosuppressed children. Kingella kingae, a fastidious gram-negative coccobacillus that colonizes the respiratory and oropharyngeal tracts in children, has been implicated as a common cause of osteoarticular infections in young children. Culture and K. kingae–specific polymerase chain reaction (PCR) assay were used by Chometon and colleagues to identify K. kingae as the causative agent in 45% of osteoarticular infections in their series.52 Studies from Israel indicate that 40 to 50% of culture-negative septic arthritis cases in children younger than 2 years of age may potentially be attributable to K. kingae.53 Fortunately, K. kingae is susceptible to a wide array of antibiotics that are given empirically to young children for septic arthritis.

The clinical picture of septic arthritis varies with age: Infants tend to have fever, failure to feed, lethargy, pseudoparalysis of the extremity, and pain with diaper changes. In one study, however, neonates (younger than 1 month) were found to have less fever and fewer systemic signs of illness than in older infants, thus making the diagnosis even more difficult.55 Most older children have systemic signs and symptoms of fever, malaise, poor appetite, and irritability, as well as localized symptoms of pain and limp or refusal to walk. With septic arthritis, the onset of symptoms is more acute than with osteomyelitis. Physical examination reveals local erythema, warmth, and swelling. If the hip is affected, it often is held in flexion, abduction, and external rotation. Range of motion is decreased because of pain and muscle spasm, and passive joint movement is painful. In infants, joint dislocation may be observed.

Laboratory studies helpful in diagnosing septic arthritis include a white blood cell count, ESR, CRP assay, blood cultures, and evaluation of joint fluid. Use of the white blood cell count and ESR is discussed in the section on transient synovitis. It should be noted that the ESR rises 24 hours or more after the onset of signs and symptoms of infection, so it may not be helpful during the first day of illness. CRP levels may be a better monitor than the ESR for septic arthritis. The CRP assay is a simpler test that requires only a fingerstick sample.

of blood. The CRP level rises more quickly than the ESR, typically is elevated at the time of the initial evaluation, and, with appropriate therapy, will normalize within a week; by contrast, the ESR will not normalize for more than a month. In patients with septic arthritis, the peripheral white blood cell count, ESR, and CRP generally are elevated, although occasionally CRP is normal, especially with *K. kingae* infection.

Blood cultures should be included in the evaluation of a child with suspected septic arthritis. Culture results are positive in 20 to 50% of cases, when positive they not only help direct antibiotic treatment but also provide an organism for serum bactericidal testing as the child progresses to oral antibiotics.

If *N. gonorrhoeae* infection is suspected, special media are required for cultures of joint fluid, blood, pharynx, skin lesions, cervix, urethra, vagina, and rectum. Urine, urethral, cervical, and vaginal specimens also can be obtained for nucleic amplification testing.

If the patient has signs or symptoms of pharyngitis, a throat swab should be sent for culture of *S. pyogenes*. Antibody titers to antistreptolysin O and anti-DNAase B also may be helpful in establishing a causative organism.

Evaluation of synovial fluid is the standard modality for diagnosing septic arthritis. If septic arthritis is being considered, joint aspiration should be performed without delay and the sample sent for Gram's stain, aerobic and anaerobic cultures, cell count with differential count, glucose determination, and a mucin clot test. The mucin clot test is a test of the integrity of hyaluronic acid, which tends to be degraded when bacteria are present. It is performed by placing two drops of 5% acetic acid into a mixture of 4 mL of water and 1 mL of synovial fluid while stirring with a glass rod. A normal result is formation of a tight rope of mucin. The test result is considered positive for infection if the fluid's consistency changes to that of curdled milk as the clot flakes and shreds. Abnormal mucin clot test results are found with septic arthritis and rheumatic fever; however, with rheumatic fever, a fibrous band resembling a tethered rope forms on the glass stir rod. The synovial fluid in patients with septic arthritis tends to be turbid or grossly purulent, with a white cell count greater than 40,000 cells/µL and a predominance of polymorphonuclear cells. Synovial glucose may be low (synovial fluid glucose: blood glucose less than 0.5) and protein and lactate elevated (Table 174-7). Because of the intrinsic immunoglobulins in the synovial fluid, results on culture of the fluid will be positive in only one half of the children in whom the clinical picture is consistent with septic arthritis. Joint fluid should be inoculated directly into blood culture bottles to enhance identification of fastidious organisms such as *K. kingae*. Culture specimens may need to be incubated for a week or longer.

In septic arthritis, plain radiographs of the hip may be normal in appearance or, in the presence of a large joint effusion, may show periarticular soft tissue swelling, widening of the joint space, obliteration or displacement of the gluteal lines, and asymmetrical fullness of the iliopsoas and obturator soft tissue planes. Late in the course of infection, subchondral bone erosions and narrowing of the joint space are seen. Ultrasonography is much more sensitive than plain radiography for detecting hip effusion and provides direct visualization of the fluid and needle during joint aspiration. Scintigraphy also may be useful in diagnosing septic arthritis; during the “blood pool” or delayed images of the joint, symmetrical uptake in periarticular tissue on both sides of the joint is seen. Scintigraphy is diagnostic of septic arthritis earlier than other imaging techniques and is a useful adjunct in identifying associated osteomyelitis or avascular necrosis of the femoral head. CT can confirm the presence of an effusion but does not differentiate septic from nonseptic arthritis. Changes in signal intensity and femoral epiphysis perfusion seen on MRI may provide diagnostic clues in attempting to differentiate septic arthritis from transient synovitis.

Septic arthritis requires immediate hospital admission, antibiotics, and surgical intervention. Surgical options range from needle aspiration to open surgical drainage, but no randomized, controlled trials have compared these two treatment approaches. Some experts recommend surgical drainage in all infants and young children with septic arthritis, because needle aspiration has been shown to be inferior in this population.

Indications for surgical drainage in children with septic arthritis include involvement of the hip joint, the presence of large amounts of pus or debris in the joint, loculated fluid, recurrence of joint fluid after four or five aspirations, and lack of clinical improvement within 3 days of the initiation of appropriate therapy. In joints other than the hip, the need for surgical drainage is determined on a case-by-case basis.

Empirical antibiotic therapy for septic arthritis is directed against the most likely organisms as dictated by patient age and comorbid conditions (see Table 174-6). Treatment may then be changed after culture and sensitivity results are known. If a pathogen is not isolated but the patient is improving, initial antibiotic therapy is continued. If a pathogen is not identified and the patient is not improving, reaspiration of the joint or the possibility of a noninfectious process should be considered. To maximize culture results, antibiotics should not be given until a specimen of joint fluid is obtained. Initial treatment should be parenteral to ensure adequate serum antibiotic concentrations. After the patient's clinical condition is stabilized, oral antibiotic therapy can be instituted. In general, doses two to three times those used for mild infections are sufficient. Response to therapy is measured by clinical improvement and assays for acute phase reactants (CRP and ESR).

The mortality rate associated with septic arthritis has fallen to less than 1%, but the morbidity remains significant. Sequelae

include leg length discrepancy, persistent pain, limited range of motion and ambulation, and ischemic necrosis of the femoral head. Predictors of a poor outcome include infection of the hip and shoulder, adjacent osteomyelitis, a delay of 4 days or more before antibiotic and surgical intervention, and prolonged time to sterilization of synovial fluid.

**Legg-Calvé-Perthes Disease**

Idiopathic avascular necrosis of the proximal femoral epiphysis, also known as Legg-Calvé-Perthes disease, is named after the men who independently described it in the early 1900s. It usually occurs between the ages of 3 and 12 years, with the peak incidence between the ages of 5 and 7 years. Legg-Calvé-Perthes disease has been reported in teenagers, as well as in children as young as 2 years. Boys are affected three to five times more frequently than girls, and the disease is familial approximately 10% of the time. The disorder is bilateral in up to 20% of cases. Legg-Calvé-Perthes disease is associated with breech presentation, later birth order (with the third to sixth children in a family particularly affected), lower socioeconomic status, higher parental age, lower birth weight, attention-deficit/hyperactivity disorder, delayed bone age, short stature, lower socioeconomic status, higher parental age, lower birth weight, attention-deficit/hyperactivity disorder, delayed bone age, short stature, passive smoke inhalation, infection with human immunodeficiency virus, and chronic renal disease. The increased incidence of Legg-Calvé-Perthes disease in Japanese, Asians, Eskimos, and central Europeans and the decreased incidence in Native Australians, Native Americans, Polynesians, and African Americans suggest that racial factors also may play a role. Trauma often is related to the onset of symptoms, but a direct relationship between the two has not been clearly established. Thrombophilia also may be associated with Legg-Calvé-Perthes; however, studies are conflicting.

Despite extensive research, the etiology of Legg-Calvé-Perthes disease remains unclear. Ponseti and colleagues suggested that the disease is a local manifestation of a transient generalized disorder of epiphyseal cartilage. Their histologic studies showed thickening and disorganization of the growth plate, which could block penetration of the blood vessels and render the femoral epiphysis avascular. Other etiologic theories involve abnormalities in the vascular anastomotic network around the femoral epiphysis, increased blood viscosity leading to infarction, and abnormalities in growth hormone.

On clinical examination, children with Legg-Calvé-Perthes disease initially exhibit a limp of insidious and stuttering onset. Associated pain, when present, usually is related to activity and relieved by rest. The pain tends to be localized to the groin or referred to the anteromedial aspect of the thigh or knee region. Symptoms and limp severity usually are worse at the end of the day. On examination, children have limited hip motion, particularly abduction and internal rotation. Early in the course of disease, the limited abduction is secondary to synovitis and muscle spasm. As the disease progresses, limitation of motion is due to deformity of the femoral head, and with time, the limited abduction may become permanent. Children with Legg-Calvé-Perthes disease demonstrate a positive result on Trendelenburg testing (see the earlier section, “Developmental Dysplasia of the Hip”) accompanied by thigh, calf, and buttock atrophy related to disuse. With advanced disease and femoral head collapse, limb length discrepancy may be noted.

The role of laboratory evaluation in the diagnosis of Legg-Calvé-Perthes disease is limited to ruling out other causes of hip pain (e.g., septic arthritis) when the diagnosis is in question or to evaluating for hormonal, metabolic, or genetic causes in patients with bilateral hip involvement.

Legg-Calvé-Perthes disease is diagnosed and staged by plain radiographs obtained in the AP and frog-leg lateral views. This radiographic survey shows the extent of epiphyseal involvement and the stage of the disease and also provides prognostic information. Radiographic “head at risk” signs that are associated with poor results include a radiolucent V-shaped defect in the lateral epiphysis and adjacent metaphysis (Gage sign), speckled calcification lateral to the capital epiphysis, diffuse metaphyseal reaction (metaphyseal cysts), lateral capital femoral epiphysis subluxation, and a horizontal physi.

These prognostic signs help guide treatment. In early Legg-Calvé-Perthes disease, radionuclide bone scanning may be diagnostic before the development of abnormalities on plain film. Bone scintigraphy also has been shown to provide accurate information concerning the extent of the necrotic process, as well as the degree of vascularization and hence the stage of the disease. Scintigraphy, however, was not able to predict disease outcome. When compared with plain radiographs and bone scan, MRI gives earlier and more reliable information about the extent of necrosis of the femoral head. MRI also is better than scintigraphy at showing revascularization. Despite the usefulness of MRI in early Legg-Calvé-Perthes disease, its role in healed Legg-Calvé-Perthes disease is limited because it provides no additional information regarding the configuration and structure of the femoral head beyond that from plain radiography. Arthrography is useful in delineating flattening of the femoral head, demonstrating the hinge abduction phenomenon with abduction of the leg, and, in conjunction with plain films or CT, diagnosing osteochondritis dissecans after Legg-Calvé-Perthes disease.

There are four radiographic classification stages of Legg-Calvé-Perthes disease: initial, fragmentation, reossification, and healed. Radiographic findings in the initial stage include a femoral head that appears smaller than the opposite unaffected femoral head, widening of the medial joint space, a subchondral lucent zone (subchondral collapse—the so-called crescent sign), an irregular physeal plate, and a blury and radiolucent metaphysis (Fig. 174-24). In the fragmentation phase, the repair aspects of the disease become more prominent. The epiphysis begins to fragment, and areas of increased radiolucency appear as new bone forms, as well as areas of increased radiodensity. During the reossification stage, the repair process continues as normal bone density returns, radiodensities replace radioluencies, and alterations in the shape of the femoral head and neck become apparent. The healed stage is the final radiographic stage of Legg-Calvé-Perthes disease, and radiographs of the proximal one third of the femur obtained during this stage of the illness will demonstrate any residual deformities.

Multiple prognostic classification systems of Legg-Calvé-Perthes disease have been devised. In general, a poor prognosis is associated with a greater degree of deformity of the femoral head and acetabulum at maturity, disease onset in
children 6 to 8 years of age or older, female gender, and prolonged duration of disease.

When the diagnosis of Legg-Calvé-Perthes is suspected, orthopedic consultation is recommended. Goals in the treatment of Legg-Calvé-Perthes disease are to improve range of motion, prevent deformity, limit growth disturbance, and prevent degenerative joint disease. Treatment is not indicated in all affected children, but when indicated, it must be started in the initial or fragmentation phase of the disease. Treatment is recommended for patients who have a poor prognosis based on clinical and radiographic findings. The cornerstone for treatment of Legg-Calvé-Perthes is referred to as “containment”: The femoral head is contained within the acetabulum to equalize pressure on the head and subject it to the molding action of the acetabulum to maintain the spherical nature of the femoral head. Containment can be achieved through nonoperative or operative methods, and optimal treatment is determined on a case-by-case basis.

Residual deformities resulting from Legg-Calvé-Perthes disease follow four patterns: coxa magna, premature physeal arrest, irregular head formation, and osteochondritis dissecans. Despite these deformities, most patients with childhood hip disease are capable of bony remodeling with subsequent improvement in femoral head deformities. During their early years, regardless of radiographic appearance, patients with Legg-Calvé-Perthes disease tend to do well. A majority (70 to 90%) of patients are active and pain-free and have good range of motion 20 to 40 years after the onset of symptoms. Only patients with flattened irregular femoral heads at the time of primary healing or premature physeal closure experienced clinical deterioration and increasing pain. Later in life, function becomes markedly reduced, with degenerative joint disease developing in a majority of patients by their 50s and 60s. With noncontainment treatment, however, the outcome is not as good. Yrjönen found that at an average of 35 years of follow-up, 48% of patients had evidence of degenerative joint disease and 17% either had undergone total hip arthroplasty or had clinical symptoms that warranted total hip arthroplasty.

Slipped Capital Femoral Epiphysis

SCFE refers to posterior and inferior slippage of the proximal femoral epiphysis on the metaphysis. The femoral head sits securely in the acetabulum, whereas the epiphysis separates from the femoral neck through the growth plate. The average annual incidence of SCFE ranges from 0.2 (in Japan) to 10.8 (in the United States) per 100,000 children, with boys being affected almost twice as frequently as girls. The peak incidence is during the adolescent growth spurt: boys between 12 and 16 years of age (mean age, 13.5 years) and girls between 10 and 14 years of age (mean age, 11.5 years). The age at diagnosis decreases with increasing obesity. A majority of children with SCFE have delayed skeletal maturation, with bone age being as much as 20 months behind chronologic age. African American and Hispanic children are affected more frequently than white children. The literature reports SCFE to be bilateral in up to 80% of cases, although 30 to 40% of these cases are asymptomatic and discovered only on screening radiographs. In unilateral cases, the left hip is affected twice as often as the right.

SCFE is associated with endocrine disorders (hypothyroidism, panhypopituitarism, hypogonadism, and growth hormone administration), renal osteodystrophy, and radiation therapy. Most cases of SCFE, however, are idiopathic and associated with obesity. The etiology of idiopathic SCFE is unknown. It is likely to be multifactorial and related to biomechanical factors such as obesity and physeal architecture, as well as hormonal factors that weaken physeal strength. Obesity results in increased shear forces across a more vertically and posteriorly oriented growth plate that has been weakened by architectural irregularities and hormonal changes of puberty. The consequence is slippage of the epiphysis inferiorly and posteriorly in the direction of the weight-bearing force.

The traditional classification of SCFE was based on the duration of symptoms, with acute slippage defined as symptom duration of less than 3 weeks, chronic slippage defined as symptoms for 3 weeks or longer, and acute-on-chronic slippage defined as symptom duration of more than 3 weeks with a recent sudden exacerbation. This classification has been replaced by one based on stability; in stable SCFE, ambulation is possible (with or without crutches), whereas in unstable SCFE, ambulation is not possible (with or without crutches).

This classification system is preferred over the traditional classification because it does not rely on patient or parent recall for duration of symptoms and provides information regarding prognosis.

The signs and symptoms of SCFE vary with its stability. Children with stable SCFE have symptoms of intermittent limp and pain of several weeks’ to months’ duration. Stable SCFE is found in approximately 95% of all cases. The pain of SCFE may be localized to the hip but more commonly is poorly localized to the thigh, groin, or knee. Atypical manifestations of SCFE include weakness and easy fatigability of the affected limb and limping on exertion. With continued slippage, internal rotation, flexion, and abduction are lost, and parents and children may note progressive external rotation and shortening of the involved lower extremity with subsequent difficulty in daily activities such as tying shoes. On examination, children initially have a slight loss of internal rotation and experience pain only at the extremes of motion. Their gait is antalgic, and muscle atrophy is minimal. As the slip becomes more severe, the gait becomes more antalgic, internal rotation is lost, abduction and flexion of the hip increase, thigh and gluteal muscle atrophy is more pronounced, and leg length discrepancy develops. A frequently seen sign associated with SCFE can be elicited during passive flexion of the affected hip: As flexion is increased from an extended position, the thigh abducts and externally rotates.

Unstable SCFE in children typically initially comes to attention after a sports-related injury or a fall with a twisting injury. These children experience acute onset of extreme pain and, on examination, hold the hip in flexion, external rotation, and abduction. The children resist any type of movement of the affected leg, and if unstable SCFE is suspected, no passive movement should be attempted for fear of further displacing the epiphysis.

The diagnosis of SCFE is made with AP and lateral radiographs of both hips. With stable slippage, AP and frog-leg lateral pelvic radiographs should be obtained. When an unstable slip or a minimal slip is suspected, a cross-table radiograph replaces the frog-leg lateral view. Early in the course of SCFE, the initial slippage is posterior, so the AP view is normal in appearance or shows widening of the physes; the slip is better seen on the lateral projection (Fig. 174-25). Early findings on lateral radiographs include a minimal posterior step-off at the anterior physeal plate or widening of the growth plate. On AP radiographs, signs of slippage include Klein’s line and the blanch sign of Steele. Klein’s line is a line drawn along the superior margin of the femoral neck. With a normal hip, the line intersects with or falls within the epiphysis, whereas in a hip with a slipped epiphysis, the line does not come in contact with the epiphysis. The blanch sign of Steele is a crescent-shaped area of increased density in the proximal portion of the femoral neck that is created by superimposition of the
The apophysis is a cartilaginous structure that serves as a site for insertion of tendons on the growing bone. It has its own growth plate that has a slower rate of growth than the nearby epiphyseal plate. Apophysitis is a condition that can occur when the apophysis is irritated or inflamed. The symptoms of apophysitis may include pain, swelling, and tenderness in the affected area.

Next, a line is drawn along the midshaft of the femur. The epiphyseal-shaft angle is formed by the intersection of the perpendicular and the femoral shaft lines. The magnitude of slip displacement is the angle of the involved hip minus the angle of the normal hip. If involvement is bilateral, 12 degrees is used as the control angle. Mild SCFE involves displacement of less than 30 degrees, a moderate slip is between 30 and 50 degrees, and severe displacement is greater than 50 degrees.

When SCFE is diagnosed in the ED, non-weight-bearing status is assigned immediately, and the child is provided with either crutches or a wheelchair; an urgent orthopedic consultation should be obtained. For a stable slip, definitive treatment is best performed within a few days; however, hospital admission is prudent. With an unstable slip, some orthopedic surgeons recommend immediate fixation.

The goals of treatment are to prevent further slippage and achieve physeal stability, avoid complications, and maintain adequate hip function. A stable slip can be fixed with internal fixation (pinning), bone graft epiphyseodesis, corrective osteotomy, or spica cast immobilization. Most orthopedic surgeons recommend internal fixation with a single central screw. Failure of this repair is very rare and, with new techniques that avoid opening the hip joint, it has become a procedure associated with minimal blood loss and wound complications and minimal need for hospitalization and rehabilitation. Postoperatively, non-weightbearing or touch-toe weightbearing for 4 to 6 weeks is followed by a gradual return to normal activity. Running and contact sports may be resumed once the physis is closed. With unstable SCFE, controversy has arisen regarding the timing of the surgery, the optimal number of fixative devices that should be used, whether reduction should be performed, and whether preliminary traction and bedrest should be used before surgery. Treatment is dependent on the degree of slippage and the preference and experience of the orthopedic surgeon.

The two most worrisome short-term complications of SCFE are avascular necrosis and chondrolysis; the risk for either process increases with the severity of the initial slippage.74 Avascular necrosis has been reported to occur in 10 to 15% of children with SCFE. The risk is higher with unstable SCFE,75,76 greater degrees of slippage, and multiple attempts at reduction.76 In children with stable slips treated by single-screw internal fixation without reduction, reported rates of avascular necrosis are as low as zero to 5%.78 Chondrolysis occurs in approximately 5% of patients with SCFE, with an increased incidence in children with greater degrees of slippage. Chondrolysis may develop before and as a result of treatment. It should be suspected when pain and loss of motion are disproportionate to the severity of the slip. On radiographs, loss of articular cartilage may be seen. When SCFE is treated by spica cast immobilization, the rate of chondrolysis is reported to range from 19 to 67%.77,79 Approximately 50% of cases of chondrolysis will resolve; however, it may progress to such severe pain and contractures that hip arthrodesis is needed.

Other complications of SCFE include nonunion, premature closure of the epiphyseal plate, and degenerative changes. Degenerative hip arthritis develops gradually over decades and has an earlier onset with more severe degrees of slippage.

**Apophyseal Injuries**

**Perspective and Principles of Disease.** The apophysis is a cartilaginous structure that serves as a site for insertion of tendons on the growing bone. It has its own growth plate that has a slower rate of growth than the nearby epiphyseal plate. Apophysitis is
unique to patients with skeletal immaturity and involves inflammation of this actively growing bony prominence that is under great tensile stress. Common apophyseal injuries include medial epicondylitis, Osgood-Schlatter syndrome, and Sever’s disease.

Apophysitis may be secondary to a single episode of macrotrauma or may follow repetitive microtrauma to the secondary center of ossification, which causes multiple tiny avulsion fractures. This scenario sets up an inflammatory cycle that is perpetuated by continued activity and trauma to the apophysis.

Growth also contributes to the development of apophysitis. As the musculoskeletal system goes through a growth spurt, muscle development lags behind bony development. This difference in development leads to a muscle-tendon imbalance manifested as tight and inflexible muscle groups in which excessive stress is placed on the apophyseal centers at which these muscles insert.

The true incidence of apophysitis is unknown. One study found an incidence of 18% in a population of 1000 patients seen at an urban general pediatric clinic over a 4.5-month period. Another study, which looked at patient visits to a sports medicine clinic, found an incidence of 31%. Children between 8 and 15 years of age most frequently are affected, with involvement of different apophyseal centers affected at different ages.

Specific Disorders/Injuries

Osgood-Schlatter Syndrome

In 1903 Osgood and Schlatter independently reported traumatically induced apophyseal injury to the tibial tubercle in adolescents. This entity, now known as Osgood-Schlatter syndrome, is the most common of the apophyseal disorders.

It is found most commonly in boys between 10 and 15 years of age and in girls between 8 and 13 years of age and frequently is bilateral. Boys are affected more often than girls, although this trend is changing as more girls are becoming increasingly involved in competitive sports. Bilateral involvement is found in 20 to 30% of patients.

Clinically, patients with Osgood-Schlatter syndrome have tenderness, pain, and swelling at the site of insertion of the patellar tendon on the tibial tubercle. The tibial tubercle may be prominent and the quadriceps tight. Pain is worsened with activities such as running or jumping that cause the quadriceps to contract, thereby stressing the tubercle. Extension of the knee against resistance causes pain, but resisted straight leg raises are painless. Osgood-Schlatter syndrome is a clinical diagnosis, and radiographs generally are not indicated. If obtained, however, lateral radiographs of the tibial tubercle may be normal in appearance or may show an enlarged, fragmented, and irregular tibial tuberosity with or without an overlying bony ossicle. Ultrasonography, which has been proposed as a diagnostic tool by some experts, may reveal pretrivial swelling, fragmentation of the ossification center, insertional thickening of the patellar tendon, or excessive fluid collection in the infrapatellar bursa.

Treatment of Osgood-Schlatter syndrome is conservative and symptomatic. Initially, the pain can be effectively managed with ice and modification of activity, with or without nonsteroidal anti-inflammatory medications. The use of a patellar strap may help to relieve symptoms. After the acute inflammatory process has resolved, treatment focuses on strengthening and stretching of the quadriceps muscles. Mild pain during activity is not an absolute contraindication to participation; however, with more severe symptoms, the risk of avulsion of the tibial tubercle should be weighed against the benefits of competing. In rare instances, conservative therapy is insufficient and a 2- to 3-week trial of crutches is required. Steroid injections have been used in the past but are not currently recommended owing to the associated risk of patellar tendon rupture. Complete recovery without residual pain or weakness is the rule. Recovery usually occurs within weeks but, in some cases, may not be complete until the underlying growth plate is closed. However, if the patient reaches skeletal maturity and is still symptomatic, consideration should be given to surgical removal of the tibial tubercle or the bony ossicle overlying the tibial tubercle (or both).

Sever’s Disease

Sever’s disease is an apophysitis of the calcaneus due to traction by the gastrocnemius-soleus complex. It initially was described in 1912 and commonly manifests as posterior heel pain in an 8- to 13-year-old athlete. It is bilateral in 60% of cases. As with other apophyseal injuries, pain is exacerbated by activity. Sever’s disease can be associated with growth or tight heel cords or other biomechanical abnormalities. Impact sports, especially those that involve running, and sports in which cleats are worn frequently are implicated in the development of Sever’s disease.

Patients have pain at the insertion site of the Achilles tendon and plantar fascia on the calcaneus. Tenderness is elicited when the calcaneus is squeezed bilaterally. Dorsiflexion of the ankle is restricted due to tight heel cords. Radiographs may be normal in appearance or may show partial fragmentation and increased density of the calcaneal apophysis, although these findings also can be seen in normal feet.

As in Osgood-Schlatter syndrome, treatment of Sever’s disease is conservative and symptomatic. Treatment consists of ice, massage, stretching of the plantar fascia and involved muscles (gastrocnemius-soleus complex and ankle invertors or evertors), nonsteroidal anti-inflammatory drugs, and addition of shock-absorbing shoe inserts. Heel cups also have been found to be helpful, but they must be accompanied by stretching to avoid exacerbating the calf muscle contracture. Patients in whom conservative management fails have been found to have bone bruising and edema in the calcaneal metaphysis and apophysis, suggesting that calcaneal stress fractures may be the cause of persistent heel pain. Modification of activity and a trial of crutches for 3 to 4 weeks may be necessary. Plantar fasciitis can cause heel pain as well, but patients will experience tenderness along the plantar fascia, especially at the attachment of the fascia to the calcaneus. Treatment involves the use of anti-inflammatory agents, rest, and relaxation of the plantar fascia with heel support pads.

Little League Elbow

Little League elbow is a term used to describe a group of injuries of the elbow including apophysitis, medial epicondylitis, and osteochondritis dissecans of the radial head and capitellum. The injury involves an overuse phenomenon resulting in inflammation at the site where the forearm flexor muscles originate. As its name suggests, it commonly affects baseball pitchers in children’s leagues and is associated with overhead arm motion. It also is seen in other skeletally immature overhand athletes, including tennis players. Little League elbow is caused by the excessive forces placed on the medial side of the elbow during the late cocking and acceleration phases of throwing.

Patients tend to be preadolescents in whom pain on the medial aspect of the elbow is associated with diminished throwing effectiveness and decreased throwing distance. Examination reveals localized tenderness and swelling over the medial epicondyle and pain with resisted flexion of the
wrist. There may be a slight flexion contracture. Radiographs may be normal in appearance or may show fragmentation, sclerosis, and widening of the medial epicondylar apophysis. Treatment consists of a regimen of ice, nonsteroidal anti-inflammatory drugs, and modification of activity. Throwing is restricted until the symptoms have resolved. After resolution of the pain, the patient can begin a program of muscle stretching and strengthening, with a gradual return to throwing. During recovery, alteration of the throwing style to reduce the degree of sidearm delivery is advisable. Recovery usually takes 4 to 6 weeks. If pain returns during resumption of pitching, rest should be reinstituted. Patients with persistent pain, locking or decreased range of motion of the joint, or lateral elbow pain should be evaluated for avulsion fractures, loose bodies, and osteochondritis dissecans.

To minimize the risk of developing medial epicondylitis in children's league pitchers, the American Academy of Pediatrics recommends limiting the number of pitches to 200 per week or 90 pitches per outing; however, the USA Baseball Medical and Safety Advisory Committee recommends lower pitch counts: 75 to 125 pitches per week or 50 to 75 pitches per outing, depending on age. Preseason conditioning, use of proper pitching mechanics, and gradual increases in the amount and intensity of throwing are other preventive measures.

**Apophysitis of the Hip**

Apophysyal injuries of the hip involve sites around the hip where major abdominal and hip muscles either originate or insert: the anterior superior iliac spine, the anterior inferior iliac spine, the iliac crests, and the ischial tuberosities. Dancers and distance runners most commonly are affected. Patients with apophysitis of the hip experience dull pain near the hip that is related to activity. Treatment includes strengthening and stretching of the abdominal and hip muscles and restriction of activity.

**Avulsion Fractures**

Apophysitis tends to have an insidious onset; therefore, any patient with sudden onset of apophysyal pain after an acute traumatic event should be evaluated for an avulsion fracture of the apophysis or the adjacent bone. Such fractures occur when the muscular attachments to the apophyses are pulled off during strong active contractions against resistance, such as with a single powerful throw. Examination will reveal localized tenderness and swelling. The diagnosis usually is readily apparent on plain films (Fig. 174-26); however, bone scan and ultrasonography may play a role when the diagnosis is in question. Ultrasonography is advantageous because it involves no radiation exposure, it can detect a fracture before the development of an ossification center, and it provides a dynamic examination. Findings consistent with an avulsion fracture include a hypoechogenic zone, increased distance to the apophysis, dislocation of the apophysis, and mobility of the apophysis on dynamic examination. Treatment of an avulsion fracture is based on the degree of separation: If the displacement is minimal (less than 2 cm with a hip avulsion and less than 5 mm with avulsion of the medial epicondyle), immobilization for 4 to 6 weeks with subsequent slow resumption of activities usually is sufficient. With widely separated avulsion fractures, some experts recommend open reduction and fixation.

---

**KEY CONCEPTS**

- Knowledge of the pediatric musculoskeletal system is imperative for appropriate evaluation and treatment of the skeletally immature patient.
- Child abuse must be suspected in children younger than 3 years with nonsupracondylar humerus fractures, femur fractures, rib fractures, and complex skull fractures.
- Children with displaced supracondylar fractures are at significant risk for neurovascular injury and should have frequent evaluations to assess for compartment syndrome.
- All children who are not yet walking should have a thorough hip evaluation on any visit to the ED.
- All patients with a gait disturbance need a thorough physical examination and directed laboratory and radiographic evaluation.
- Septic arthritis constitutes a medical and surgical emergency that mandates immediate orthopedic consultation.
- Examination of the hip is warranted in all patients with knee pain.

General Approach to the Pregnant Patient

Laurie J. Morrison

Section Two • The Pregnant Patient

Chapter 175

Perspective

Epidemiology

Remarkable trends in the epidemiology of fertility have emerged that may have an impact on the demographic and diagnostic profile of patients encountered in today’s emergency department (ED). The birth rates and fertility rates for all races, and the mean age at menarche in both the United States and Canada have fallen over the past decade. The age-specific fertility rate has declined in women younger than 30 years, and the rate of multiple births is rising.

The National Center for Health Statistics reported the number of U.S. live births for the year ending December 2005 to be 4.12 million with a birth rate of 14 per 1000 population for all races. In Canada during the year 2006-2007, the birth rate was 10.8 per 1000 population, with 352,848 births. Over the past 5 years Canada has witnessed a rise in the birth rate, with the mean age for mothers giving birth of 29.2 years. Women aged 30 to 34 years of age contributed 31.4% of this growth, whereas fertility rates in women younger than 20 years of age continue to decline. The 2008 report from the U.S. National Center for Health Statistics noted that the birth rate for women younger than 25 years, the principal childbearing age, had fallen from 43% in 1990 to 38% in 2004. The overall birth rate for teens aged 15 to 19 dropped from 15% in 1990 to 12% in 2004, which resulted in a historic low of 72 pregnancies per 1000 women. Nearly one half of all pregnancies in the United States occur among unmarried women, and this number is rising, increasing from 2.7 million in 1990 to 2.8 million in 2004, whereas rates among married women continue to fall, from 4.1 million in 1990 to 3.5 million in 2004. Pregnancy outcomes in the United States vary across the black, Hispanic, and white populations. The rate of pregnancies resulting in live births varies from 69% in non-Hispanic whites and 98% in Hispanic women to 50% for non-Hispanic blacks, whereas the rate of pregnancy resulting in abortion in non-Hispanic blacks is triple the rate (37%) for non-Hispanic whites (12%) and Hispanic women (19%).

Definitions

Gestational age refers to the number of completed weeks of pregnancy from the last menstrual period. A term infant is a child born between 38 and 42 completed weeks of gestation, a preterm infant is born before 38 completed weeks of gestation, and a post-term infant is born any time after 42 weeks’ gesta-
occurs beyond 42 or 43 weeks’ gestation. Labor occurs before 37 weeks’ gestation, and 10% denied being sexually active. Adolescents rarely mentioned the possibility of pregnancy at triage (10%), failure to document a sexual or menstrual history. Adolescents with a diagnosis of pregnancy in adolescents was associated with notably poor. Ramouska and colleagues reported that 11.5% of women who ingest estrogen-progestin contraceptives. Abdominal striae occur not only in pregnancy but also in nonobese women. The only changes are seen in the lower portion of the uterus. It is a function of blood flow through the dilated uterine vessels and can be heard in pregnancy and in women with uterine myomas or large tumors of the ovaries.

Breast tenderness and fullness are common manifestations of pregnancy that can be appreciated on gentle physical examination. Objective breast changes include darkening of the areolae, greater prominence of the breasts with tiny bluish venules, and presence of colostrum at the nipple with gentle massage of the breasts. This milky material may persist for months or even years, especially if the patient continues to breast-feed.

Increased skin pigmentation (melasma gravidarum) and abdominal striae occur not only in pregnancy but also in women who ingest estrogen-progestin contraceptives. Braxton-Hicks contractions are painless contractions that occur spontaneously and irregularly early in pregnancy. They also occur in patients with hematometra and those with uterine myomas. These contractions are not reliable for the diagnosis of pregnancy; however, they do not occur in ectopic preg-
nancy, so their presence may be helpful in excluding the existence of an ectopic pregnancy.9

Uterine enlargement can be felt in nonobese women. At 6 to 8 weeks the uterus is approximately the size of an orange. At 12 weeks the top of the fundus should be at the level of the symphysis pubis, at 16 to 20 weeks at the level of the umbilicus, and at 36 to 38 weeks at the level of the xiphoid process of the sternum. Thereafter, the fetus descends into the pelvis, and fundal height may decrease accordingly.12

At approximately 6 to 8 weeks of pregnancy, Hegar’s sign can be appreciated during an internal pelvic examination. Hegar’s sign is softening of the lower uterine segment caused by hyperemia. In some cases the softening is sufficient to allow the examiner to easily distinguish the cervix from the fundus on palpation. It can be found in other conditions; however, it is not as easily detected as it is in pregnancy (Fig. 175-2).

The vaginal mucosa becomes hyperemic during pregnancy and with any other condition that causes congestion of the pelvic organs. In response, the color of the mucosa of the vaginal walls changes from pink to blue to violet and can be visualized at the vaginal introitus (Chadwick’s sign).13

At midpregnancy the fetus can be detected by ballottement or palpated through the maternal abdominal wall in a nonobese patient. The fetus floats in a large volume of amniotic fluid. Thus, with ballottement, pressure exerted on the uterus causes the fetus to sink and then rebound to its original position. Palpating the outline of the fetal body becomes easier near the end of pregnancy; however, subserosal myomas can simulate the fetal head and small parts, or both.9

■ DIAGNOSTIC STRATEGIES

Laboratory Tests

Determination of urine or serum human chorionic gonadotropin (hCG) is important in clinical management. Applications include diagnosis and monitoring of pregnancy and diagnosis and evaluation of the course of neoplastic trophoblastic disease or response to treatment (i.e., hydatidiform choriocarcinoma, gonadal teratoma, a carcinoma with ectopic secretion of hCG).14

Human CG assays are referenced to standard hCG preparations. Thus, the reference standard should always be noted in comparing results. One nanogram of hCG equals 9.3 mIU of the international reference standard provided by the World Health Organization (used in this chapter) and equals 5.0 mIU of the second international standard.15

Biologic assays for hCG are now only of historical interest. Since the 1960s, all hCG assays have been immunoassays. Enzyme-linked immunosorbent assay (ELISA) for hCG is the state-of-the-art pregnancy test. ELISA offers greater user convenience and has a sensitivity for levels of hCG between 25 and 50 IU/L.

Over the years the pregnancy test has undergone a number of refinements. Antibodies are selected that act against the purified β subunit of hCG, and this modification has resulted in improved sensitivity for low levels of hCG in the presence of luteinizing hormone. The development of monoclonal antibodies has improved specificity for the purified β subunit of hCG.

The fundamental process of ELISA involves an antibody adherent to a solid-faced support (usually plastic) that binds to a region of the hCG molecule. A second antibody chemically linked to an enzyme (for example, alkaline phosphatase) binds to another side of the trapped hCG molecule. The hCG molecule is sandwiched between the two antibodies. Excess enzyme-linked antibody is washed away, and a color developer is added and becomes blue when it comes in contact with the enzyme (Fig. 175-3). The antibodies can be polyclonal or monoclonal. Many variations exist with respect to the solid-faced support and the method of developing the color reaction.

In 1988 the first one-step pregnancy test became available. It was developed and patented by Unipath and is sold as Clearblue One Step. This test uses monoclonal antibodies specific for the β subunit of hCG. It includes a unique built-in control that shows a blue line when the test is complete and performed correctly.16 This test appeals to consumers because it is rapid (requiring less than 5 minutes), requires no manipu-
time of the missed period essentially guarantees that a woman is not pregnant.\textsuperscript{19} For detection to occur on the day of missed menses, a lower sensitivity level of 12.5 mIU/mL is required. A study in 2001 compared routine urinary hCG point-of-care qualitative tests performed by nurses in the ED versus laboratory tests and found the former to be equally accurate and much faster, shaving 35 minutes off wait times for results.\textsuperscript{18}

A well-designed ELISA applied to urine is not affected by drugs or a concurrent physiologic state. The only exception is in patients taking exogenous hCG for induction of ovulation.\textsuperscript{19}

Normal hCG levels in men and premenopausal women range from 0.02 to 0.8 IU/L. Postmenopausal women may have higher levels.\textsuperscript{20} The blastocyst begins to secrete hCG 7 days after fertilization.\textsuperscript{21} Thus, the hCG released can be detected as early as 6 to 8 days after conception.\textsuperscript{22,23}

The initial doubling time is fast and has been attributed to the actual process of implantation. This is followed by a slower rate of doubling as trophoblast hCG and maternal circulatory hCG levels equilibrate\textsuperscript{23} (Fig. 175-4). Human CG levels peak at 7 to 10 weeks of pregnancy, with a mean value of 50,000 IU/L and a range of 20,000 to 200,000 IU/L.\textsuperscript{24}

Human CG testing becomes positive in 98% of patients 7 days after implantation, which coincides with the time of the expected period. When a test with a sensitivity of 25 to 50 IU/L is used, a negative result 1 week from the expected time of the missed period essentially guarantees that a woman is not pregnant.\textsuperscript{19}

The minimum number of false-positive results can be attributed to postmenopausal status, abortion in the first trimester, exogenous hCG for induction of ovulation, or an hCG-secreting tumor. Levels of hCG may take as long as 60 days to return to zero after an abortion.\textsuperscript{25} Persistent elevation of hCG beyond 60 days after abortion may indicate an incomplete abortion, a twin pregnancy with only one fetus removed, or an ectopic pregnancy.\textsuperscript{4}

The hCG assay continues to be the standard for the diagnosis of pregnancy. Routine clinical detection of pregnancy by ultrasonography is not possible until 6 weeks’ gestation, when the hCG level is 1000 IU/L or more.\textsuperscript{26-28}

**Radiology**

**Ultrasonography**

Ultrasonography is reliable for the diagnosis of intrauterine pregnancy during the first trimester. In addition to diagnosis, it also locates the embryo and assesses gestational age and viability. Transabdominal sonography is more commonly used; however, transvaginal sonography may be necessary during the first trimester if transabdominal sonography is not diagnostic.

Sonography during the second trimester is used to survey fetal anatomy. The anatomic survey includes the cerebral ventricles, four-chamber view of the heart, spine, stomach, urinary bladder, umbilical cord insertion on the abdominal wall, and kidneys.\textsuperscript{29}

Much debate exists about whether ultrasonography should be performed as part of routine prenatal screening in all pregnancies. The National Institutes of Health Consensus Conference in 1984 concluded that sonographic studies performed during pregnancy are safe.\textsuperscript{30} Genetic screening of pregnancy requires an accurate gestational age based on biparietal diameter; accordingly, ultrasonography at 15 to 16 weeks is a routine component of maternal genetic screening.

**Transabdominal Sonography.** Transabdominal ultrasound examination at 4 to 5 weeks of gestation can identify the presence of a small white gestational ring. This sonographic finding disappears after the 11th week of gestation.\textsuperscript{9}

At 6 weeks the gestational sac can be visualized by transabdominal sonography (Fig. 175-5). Presence of the sac is con-

![Figure 175-4](image1.png)  
**Figure 175-4.** Levels of circulating human chorionic gonadotropin (hCG) in early pregnancy, showing that an assay with a sensitivity level of 25 IU/L would yield a positive result in some subjects between 10 and 11 days after the peak in luteinizing hormone (LH) and in most subjects at 12 to 13 days after the peak. (Modified from Chard T: Pregnancy tests: A review. Hum Reprod 7:701, 1992.)

![Figure 175-5](image2.png)  
**Figure 175-5.** Transabdominal ultrasound image showing a gestational sac with no fetal pole or yolk sac. (Courtesy of Andrew A. Common, MD.)
firmed when two central uterine echoes are visualized within the hypertrophied endometrium. This diagnostic echo is called the double decidual sac sign. A healthy pregnancy can be determined by correlating the size of the sac with gestational age and quantitative hCG values. At 8 weeks the fetal pole and fetal heart activity can be visualized reliably with transabdominal ultrasonography in a normal pregnancy.

**Transvaginal Sonography.** Transvaginal sonography affords greater resolution than transabdominal sonography and does not require a full bladder. Transvaginal ultrasound examination can identify an intrauterine gestational yolk sac at 5 weeks’ gestation. This finding correlates with a quantitative hCG value of more than 1800 IU/L. Fetal heart motion can be detected with transvaginal ultrasound evaluation at 6 weeks’ gestation and correlates with an hCG level of 6770 IU/L and a crown-rump length of 2 mm.

An intrauterine pregnancy can be diagnosed by sonographic findings in the following order of appearance: the double ring sign, the double gestational sac, the intrauterine fetal pole, and intrauterine fetal heart activity (Fig. 175-6). The gestational sac is eccentrically positioned within an asymmetrically thickened decidua. An ectopic pregnancy can be difficult to distinguish from a normal pregnancy and may be seen sonographically as a pseudosac or fluid collection centrally placed in the uterine cavity and surrounded by symmetrically thickened endometrium.

**Magnetic Resonance Imaging**

No significant side effects have been documented to date with the magnetic field and radio waves used in magnetic resonance imaging (MRI). Gadolinium is the most common intravenous contrast agent, and allergic reactions with this agent are rare. The effects of strong magnetic fields on the fetus are unknown, so the consensus is that use of this imaging modality should be avoided in pregnant women.

**Plain Radiographic Fetal Identification**

The fetus can be reliably recognized by plain radiography after 16 weeks’ gestation. Fetal foci of ossification can be identified as early as 14 weeks.

**Diagnostic Imaging Considerations in Pregnant Patients**

The decision to perform imaging investigations in a pregnant patient must take into consideration the risk to the developing fetus from radiation exposure and the inherent risks with such investigations for the mother, balanced with the risk to the mother and fetus associated with missing the diagnosis because of reluctance to use available diagnostic imaging techniques. The potential for adverse outcomes with intraterine fetal exposure to the radiation used in radiography is minimal. Case-control studies report a slight but statistically significant increase in the relative risk for childhood cancer. Radiation is a dose-dependent teratogen. The fetal central nervous system is most vulnerable to the teratogenic effects of radiation at 8 to 15 weeks after conception. The fetal dose of radiation is estimated from the ovarian or uterine dose. Pregnant women exposed to less than 5000 mrad have pregnancy outcomes similar to those in control subjects. A study of childhood cancers in the offspring of female radiologists revealed a cancer frequency of 0.16% in children exposed to 1000 mrad of radiation in utero. In comparison, the frequency of cancer is 0.07% among children who were not exposed to radiation in utero.

Table 175-1 summarizes the estimated fetal radiation exposure associated with the more common diagnostic imaging modalities. Radiation exposure depends on the equipment and technique, and estimates listed may not be generalizable to every radiology department.

A thoughtful, common-sense approach to the differential diagnosis will provide a sound basis for imaging investigations that will undoubtedly be in the best interests of the mother and the fetus. It is important not to defer investigations that are medically necessary, so long as the anticipated fetal doses are less than 5000 mrad.
Considerations in the differential diagnosis with early pregnancy include myomas, hematometra, adenomyosis, and an extrauterine mass or masses. Patients with these diagnoses, excluding hematometra (a blood collection or retention in the uterus), typically have persistent regular menses. The enlarged uterus in these nonpregnant conditions generally is firmer and less elastic and boggy than it is in pregnancy.\(^9\)

Spurious pregnancy is imaginary pregnancy or pseudocyesis (false phantom). It usually occurs in women nearing menopause or in women who have an overwhelming desire for pregnancy. The associated increase in abdominal girth generally is attributable to fat deposition, fluid accumulation, or intestinal gas. The menses may become unpredictable with respect to timing, duration, and amount of flow. This condition can be associated with changes in the breasts, including enlargement, galactorrhea, and increased areolar pigmentation. Patients may have morning sickness of psychogenic origin. The associated use of phenothiazines may cause amenorrhea, hyperprolactinemia, breast enlargement, and galactorrhea. Women with this condition may perceive fetal movements. Most commonly these movements can be attributed to mus-
pregnant and nonpregnant patients without previous bleeding at 0.031 per patient-year. Arteriovenous malformations usually bleed during the second trimester and during labor. Berry aneurysms initially bleed during the third trimester, and the incidence of bleeding increases as the pregnancy advances.

Nearly one third of cases of spontaneous subarachnoid hemorrhage are a result of bleeding disorders, bacterial endocarditis, metastatic tumor, and sickle cell disease. Cerebral hemorrhage is the most common cause of death in toxemia. It occurs in 60% of patients who die after becoming eclamptic.38

New-onset headache or a change in the usual pattern of headache pain during pregnancy or the postpartum period warrants a closer look. A thorough history and a detailed physical examination with emphasis on visual field and funduscopic examination can, in most cases, exclude the aforementioned serious disorders.

**Chest Pain**

The diagnosis of cardiac disease is complicated by the fact that the signs and symptoms of a normal pregnancy are suggestive of heart disease. Pregnancy is associated with easy fatigability, dyspnea, orthopnea, palpitations, syncope, peripheral edema, chest discomfort, and reflex. Triggers for further cardiac evaluation include progressive orthopnea, dyspnea severe enough to limit activity, paroxysmal nocturnal dyspnea, syncope during or immediately after exertion, hemoptysis, and chest pain in an ischemic distribution at rest or associated with exertion, anxiety, or anger.39

Cardiovascular findings are altered in normal pregnancy. Peripheral edema is present in 80% of pregnant women. A third heart sound and systolic murmurs are common. Diastolic murmurs and systolic murmurs of grade higher than II/VI warrant investigation. Other worrisome signs include cyanosis, clubbing, pulmonary rales, distended neck veins throughout the cardiac cycle associated with hepatomegaly and peripheral edema, persistent split S2, and criteria of pulmonary hypertension (left parasternal lift and a loud P2).38

The pregnant patient is predisposed to thrombolytic disease as a result of increased venous pressure, decreased distal venous flow, and significant venous stasis from compression of the pelvic veins and inferior vena cava by the enlarging uterus. Other predisposing factors may include the antepartum use of oral contraceptives before conception and the propensity for stasis secondary to lack of activity in the workplace and at home as the pregnancy progresses.9 The annual incidence of thromboembolism is five times higher in postpartum than in pregnant women.40 The incidence of deep vein thrombosis is three times higher than that of pulmonary embolism; however, the incidence of deep vein thrombosis during pregnancy has remained constant over the last 30 years, whereas that of pulmonary embolism during pregnancy doubled.40 This increased risk for pulmonary embolism in pregnancy should prompt thorough evaluation of pregnant patients who present with pleuritic chest pain, syncope, acute right-sided heart failure, or more subtle signs such as unexplained fever, dyspnea, or tachycardia.

**Abdominal Pain**

Displacement of the abdominal contents by the expanding uterus during pregnancy causes abdominal discomfort that may be associated with nausea, vomiting, gastroesophageal reflux, delayed gastric emptying, bowel irregularity, urinary frequency, and back and buttock pain. These findings may complicate the clinical assessment of a pregnant woman with abdominal pain. Delay in diagnosis or failure to diagnose and treat underlying pathologic conditions may result in maternal and fetal morbidity and death.

Obstetric causes of abdominal pain early in pregnancy include vascular congestion of the pelvic tissues, round ligament tension, ectopic pregnancy, and threatened abortion. Later in pregnancy, considerations in the obstetric differential diagnosis should include Braxton-Hicks contractions, toxemia, premature labor, abruptio placentae, and rupture of the uterus.38 Nonobstetric causes include all diagnoses seen in a nonpregnant patient (e.g., cholecystitis, pyelonephritis, renal colic, ovarian torsion, salpingitis, corpus luteum cyst rupture or torsion, degeneration of a uterine myoma). Common surgical diseases that may complicate pregnancy include appendicitis, gallbladder disease, and intestinal obstruction.

The incidence of appendicitis in pregnant patients is equal to that in nonpregnant patients, but the perforation rate is higher. The state of pregnancy results in delays in diagnosis of appendicitis that contribute significantly to maternal and fetal morbidity and mortality.47 The perinatal mortality rate for women with nonperforated appendicitis is 4.8%. It rises, however, to 27.8% in those experiencing perforation at the time of surgery. The perforation rate is as high as 30% during the third trimester.48

The diagnosis of appendicitis is more difficult during the latter half of pregnancy, but it is challenging even in early pregnancy. Anorexia, nausea, and vomiting are symptomatic of appendicitis and may be misinterpreted as hyperemesis of pregnancy. As the uterus enlarges, the appendix moves upward and outward toward the right. As the appendix moves higher, the omentum is unable to surround the appendix and contain the infection if rupture occurs. Thus, appendiceal rupture in pregnant women results in generalized peritonitis. A retrospective review comparing magnetic resonance imaging (MRI) findings with surgical confirmation of disease suggests that MRI is useful for triaging pregnant patients with acute abdominal and pelvic pain.49 When available, MRI should be considered in this setting, particularly during the first trimester of pregnancy, because of the higher levels of radiation exposure associated with computed tomography (CT) of the abdomen.

**Musculoskeletal Pain**

Hand symptoms are common during pregnancy. The median nerve is at risk for compression distally within the carpal tunnel. Approximately 25% of pregnant women complain of hand symptoms comparable with median nerve compression, but only 2.3% are actually found to have carpal tunnel syndrome.50 Symptoms of carpal tunnel syndrome include the classic triad of burning pain, numbness, and tingling in the thenar area or median nerve distribution. The patient often is awakened from sleep with the onset of symptoms. In 80% of cases, the symptoms are bilateral. Tapping over the median nerve at the wrist (Tinel sign) or hyperflexing the wrist (Phalen’s test) reproduces the symptoms and is diagnostic. Because the symptoms usually resolve during the postpartum period, only supportive treatment is required. A sleep splint applied with the hand in slight flexion resolves the symptoms in 80% of patients.51

Postural changes in the cervical spine, the shoulder girdle, and the lumbar spine result in pregnancy-related posterior pelvic pain and low back pain. Lordosis is exaggerated and becomes progressively more symptomatic during pregnancy. Low back pain usually is localized to the lumbar region just above the sacroiliac joint, worsened by forward flexion at the waist, and results in decreased range of motion and tenderness.
to palpation of the erector spinae muscles. The pain may radiate to one or both of the legs. The nature of the referred pain lacks the radicular quality of discogenic pain and does not extend beyond the knee. Patients should avoid wearing high-heeled shoes because this will increase the lumbar lordosis with exacerbation of the pain. Swimming and conditioning exercises are recommended. Pregnancy-related posterior pelvic pain is hypothesized to occur because of asymmetrical sacroiliac joint laxity. It is important to distinguish this from low back pain, because the treatments are different. Pregnancy-related pelvic pain is a stabbing pain in the buttocks, distal and lateral to the L5-S1 area, which may or may not radiate to the posterior thigh or knee, with a normal range of motion at hips and spine. The posterior pelvic pain provocation test has a positive predictive value of 0.91 for pregnancy-related pelvic pain. The test is performed with the patient in the supine position with the hips and knees bent at 90 degrees. The examiner applies pressure with one hand at the knee along the long axis of the femur from anterior to posterior while using the other hand to stabilize the pelvis at the contralateral anterior iliac spine. A positive test result is gluteal pain on the side of femoral pressure. Meralgia paresthetica is a painful dysesthesia along the lateral aspect of the thigh caused by entrapment of the purely sensory lateral femoral cutaneous nerve as it passes beneath the inguinal ligament. This condition develops during the third trimester in obese pregnant women or in pregnant women with excessive and rapid weight gain. It resolves during the postpartum period without treatment.

### Trauma

Trauma is the leading cause of death in young men and women. The American College of Obstetricians and Gynecologists reports that 1 in every 12 pregnancies is complicated by physical trauma. Trauma is the leading cause of maternal death secondary to nonobstetric etiologic conditions or disorders. One study suggests that fetal mortality after trauma is significantly associated with higher injury severity score (of 28 or higher), lower final hemoglobin level, higher number of transfusions, longer hospital stay, and a higher incidence of disseminated intravascular coagulation. A retrospective institutional review over 5 years demonstrated that older maternal age, first-trimester presentation, elevated serum lactate, and high injury severity score were associated with poor fetal outcome. Other studies have not demonstrated a correlation between injury severity scores and maternal and fetal morbidity, and their authors advocate enhanced clinical vigilance for the unexpected in caring for obstetric trauma victims (see Chapter 34).

### Domestic Violence

Up to 35% of all ED visits by women are due to injuries or illnesses related to domestic violence. Domestic violence is conservatively estimated to occur in 10 to 20% of North American spousal relationships. Estimates of abuse during pregnancy vary widely, ranging from less than 1% up to 37%. The wide variation in estimates is attributable to different study designs, definitions of abuse (Table 175-2), and sample population demographics. Moreover, it generally is accepted that violence in the home is underreported and the prevalence is higher than studies estimate.

Violence may begin or increase during pregnancy. Prevalence estimates in 1997 based on cross-sectional survey data obtained from interviews with 261 pregnant women suggest that 33.3% of women will report abuse when asked. Of the 261 women interviewed, 26.7% were African Americans, 25.2% were of Hispanic origin, and 58.3% were white women. Pregnant teenagers are at even greater risk for abuse from parents and partners. Other significant demographic variables associated with abuse and pregnancy can be classified under the major headings of social instability, unhealthy lifestyle, and physical health problems. Abused pregnant women are more commonly of lower educational levels, unmarried, unemployed, eating an unhealthy diet, abusing drugs and alcohol, and experiencing an unplanned pregnancy; they may also delay seeking prenatal care (Table 175-3). Evidence of physical abuse is more common in the facial area in a nonpregnant patient, whereas blunt abdominal trauma is the most common injury type in a pregnant patient. Blunt abdominal trauma can result in miscarriage, abruptio placenta, fetal loss, premature labor, fetal fractures, low birth weight, and premature delivery. Other common injury sites in abused pregnant patients are the breasts and genitals.

Not all abuse is physical abuse (see Table 175-2). Emotional abuse, including intimidation by the aggressor to maintain an abused woman in the abusive relationship, has been well described. Most abused women remain in the relationship, and few have any knowledge of the support services available to them. Abused pregnant women often suffer from low self-esteem, despair, anxiety, fear, withdrawal, post-traumatic stress disorder, passivity, learned helplessness, and depression and have high rates of attempted suicide.

Abused pregnant women may have vague physical symptoms, including headache, fatigue, insomnia, choking sensations, gastrointestinal complaints, pelvic pain, and backache. These symptoms may be manifestations of a deep depression or of a conversion reaction related to the adversity of the home environment.

Abused pregnant women do not believe that they have any control over the health of their fetus. They hold a strong belief that chance is the major determinant in fetal outcome. This perception and the associated behavior (e.g., cigarette smoking, alcohol and drug abuse) are unlikely to change unless the abused women leave their abusive situation. Only then will they be able to improve their sense of power and self-esteem and make changes in their behavior that are in the best interest of the fetus.

Identification and appropriate follow-up are paramount in the ED management of an abused pregnant patient. Most abused patients will not volunteer information regarding domestic violence unless specifically asked. They are more likely to disclose such information to another woman or medical

MANAGEMENT

Perspective

The assessment and care of pregnant patients require specialized equipment and access to specific ancillary tests. Basic equipment for the management of all obstetric and gynecologic emergencies includes a variety of specula and a Doppler ultrasonographic device for fetal heart readings. The specula should be available in at least four blade widths: extra narrow at 16 mm (e.g., Miltex Pedersen), narrow at 22 mm (e.g., Miltex Pedersen), regular at 25 mm (e.g., Pedersen), and wide at 35 mm (e.g., Graves). Speculum blades are available in three lengths: small at 7.7 cm, medium at 10.2 cm, and large at 17.8 cm. The medium-length Pedersen speculum provides adequate exposure for most women. Virginal or postmenopausal women may require a narrow or extra narrow speculum with a 10.2-cm-long blade. Pelvic examination of obese patients or patients in whom the vaginal walls are loose and redundant may necessitate the use of a Graves speculum.

Appropriate diagnostic imaging (transabdominal and transvaginal sonography, as well as color Doppler ultrasonography or impedance plethysmography) and laboratory testing (both quantitative and qualitative hCG testing) should be available at all times. Access to MRI should be available by previous arrangement if equipment is not on site. If ready access to a high-risk obstetric unit is not available, prearranged agreements for transport to specialized centers for high-risk obstetric patients and neonates should be in place.

Health Promotion and Disease and Injury Prevention in Pregnancy

For some patients, the ED is where the diagnosis of pregnancy is first made and the time the patient is introduced to both the emotional and physiologic realities of pregnancy. For others, the ED is simply the only source of prenatal care.

After complications of pregnancy and comorbid conditions have been excluded, pregnant patients should initially be counseled, appropriately referred, and encouraged to partici-
pate in regular prenatal care. The proportion of American women beginning prenatal care during the first trimester has consistently increased since the early 1990s, with a rate of 83.9% reported in 2004.\textsuperscript{79} Statistics suggest that timely care rose 10\% during the 1990s and continued to rise until 2003.\textsuperscript{79,81}

Although the time for prenatal counseling often is limited in the ED, such counseling can have a positive impact on both fetal and maternal health. The following discussion is not inclusive of all prenatal issues; however, it does outline some of the most commonly identified risks and patient concerns, along with the appropriate advice that should be given.

**Use of Seat Belts, Helmets, and Air Bags**

The use of three-point seat belt restraints should be emphasized. There is no evidence that these restraints will increase the chance of fetal injury. The proper use of seat belts is a good predictor of a favorable maternal and fetal outcome in the case of vehicular trauma.\textsuperscript{82} The lap belt should be snugly and comfortably placed low across the maternal pelvis, below the uterine corpus and fundus and across the thighs, with the shoulder belt positioned between the breasts and no excessive slack allowed anywhere in the belt.\textsuperscript{83} The National Highway Traffic Safety Administration does not consider pregnancy to be an indication for the deactivation of air bags and recommends the combined use of seatbelts and air bags.\textsuperscript{84} All patients should be encouraged to wear helmets when riding a bicycle or a motorcycle, whether voluntarily or in compliance with the law. The latter modes of transportation are ill advised during pregnancy and certainly inappropriate during the third trimester.

Safe infant feeding should be reinforced. It is inappropriate and unsafe to breast-feed in a moving vehicle. Similarly, it is unsafe to remove the child from the restraining device to bottle-feed while in a moving vehicle.

**Sexual Intercourse during Pregnancy**

Sexual intercourse is considered harmless for a normal pregnancy female. Most texts recommend abstinence during the last 4 weeks of pregnancy or when abortion or preterm labor is threatened.

**Safety of Douching during Pregnancy**

Certain guidelines must be adhered to for the proper use of douches during pregnancy. Hand-held bulb syringes are prohibited because of the risk of air embolism. The height of the douche bag should be limited to 2 feet or less above the level of the hips to prevent high fluid pressure. The nozzle should not be inserted more than 8 cm into the vagina.

**Travel Restrictions during Pregnancy**

Generally, travel is not prohibited during pregnancy. Airlines allow unrestricted travel for women with normal pregnancies (and no history of premature labor) up to 35 to 37 weeks of gestation. Only short trips are allowed with more advanced pregnancy and require a doctor’s letter of assurance that delivery is not imminent. It should be emphasized to the pregnant traveler that she should walk about at least every 2 hours to minimize the risk for thromboembolism. Cosmic radiation exposure for casual travelers is trivial. Pregnant airline employees or frequent flyers should consult a physician during pregnancy because their cosmic radiation exposure is increased.\textsuperscript{85}

**Immunization during Pregnancy**

The Advisory Committee on Immunization Practices posts guidelines for immunization during pregnancy on the CDC website. Immunization of pregnant women should be guided by risk-versus-benefit logic. Relative indications for vaccination consist of three guiding principles: (1) the risk of exposure is high, (2) the infection could cause harm to the mother or infant, and (3) the vaccine is unlikely to cause harm. Live virus vaccines generally are contraindicated during pregnancy because of the theoretical risk of transmission of the virus to the fetus. If a pregnant patient has received a live virus vaccine in the 3 months before the pregnancy, she should be referred for counseling on the potential risks to the fetus. Comprehensive and specific guidelines for each vaccine are updated and posted on the CDC website (http://www.cdc.gov/vaccines/pubs/ACIP-list.htm).

**Importance of Regular Appropriate Exercise**

Suitable regular exercise should be encouraged during pregnancy because it helps prevent venous stasis and thromboembolic disease, maintain regular bowel movements, improve posture and perineal muscle strength, and regulate weight gain. Sedentary lifestyles and work activities that are performed predominantly in the sitting position should be discouraged. The American College of Obstetrics and Gynecology recommends that healthy pregnant women without medical or obstetric complications adhere to the standard of exercise for nonpregnant patients recommended by the CDC and the American College of Sports Medicine. The standard aimed at improving health and well-being includes an accumulation of 30 minutes or more of moderate activity daily. Pregnant patients with comorbid conditions require exercise also and should engage in regular exercise with close medical supervision.

Patients should be encouraged to strengthen the abdominal muscles; stretch the lower part of the back; balance pectoralis muscle strength with that of the trapezius, rhomboids, and latissimus dorsi; strengthen the cervical spine flexors; and perform regular pelvic tilt exercises in all positions to correct the postural imbalance of pregnancy and relieve discomfort.

Appropriate exercise includes low-impact and aquatic aerobics. High-impact activities should be avoided, especially during the latter half of pregnancy. Aggressive abdominal exercises are discouraged after 12 weeks of gestation because they may exacerbate the development of diastasis recti. Moderate regular abdominal strengthening exercises will minimize the lordosis of pregnancy. The Aerobics and Fitness Association of America recommends that exercise intensity during pregnancy be limited to an exercise heart rate range of 55 to 70\% of the age-predicted maximum heart rate; class time should not exceed 1 hour and 15 minutes, including the time for stretching and relaxation exercises; and frequency should not exceed three times a week.

**Diet, Vitamin Supplementation, and Weight Gain Recommendations**

It is not recommended that pregnant patients take routine multivitamin supplementation; however, iron supplements may be recommended, especially during the latter half of pregnancy. It also is recommended that 1 mg of folic acid be taken daily, beginning 1 month before conception and continuing throughout the first trimester to reduce the risk for neural tube defects.

The American College of Obstetricians and Gynecologists recommends an average weight gain for pregnant women of
between 10 and 12 kg. The normal physiologic changes of pregnancy account for approximately 9 kg. The remainder is maternal fat storage. The CDC makes weight gain recommendations according to prepregnancy weight: underweight women, 13 kg; normal-weight women, 11 kg; and overweight women, 7 kg.

Appropriate Management of Pregnant Patients with Substance Abuse Problems

The risks of smoking, illicit drug use, and excessive alcohol consumption during pregnancy are widely known to the lay public; however, despite warnings, some pregnant women continue to smoke and imbibe excessively. Cigarette smoking during pregnancy has declined steadily since 1989, to 12.9% in 1998 and 10.7% in 2005. Nonetheless, tobacco use by pregnant teenagers continues to be high, with a reported rate of 19% in 2005. The U.S. Department of Health and Human Services Substance Abuse and Mental Health Services Administration concluded from its National Household Survey on Drug Abuse (1996-1997 database) that among women 15 to 44 years of age who were currently pregnant, 2.5% used one or more illicit drugs in the past month, 1.3% engaged in “binge” alcohol use, and slightly less than 20% were past-month cigarette smokers. Binge drinking was defined as drinking five or more drinks on the same day at least once during the previous 30 days. In comparison with a nonpregnant cohort, women who abuse substances reported curtailing their use during pregnancy and resuming use postpartum. Substance abuse during pregnancy was more frequent in unmarried women without a high-school education. The prevalence decreased as the amount of adult education increased. The prevalence of drug abuse during the last month of pregnancy showed no difference between Hispanic and white pregnant females. Drug abuse during pregnancy was significantly more common among black than among Hispanic patients.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
Acute complications of pregnancy can appear in all trimesters of pregnancy and can pose challenges in diagnosis and management. Life-threatening disorders of pregnancy, such as ectopic pregnancy in early pregnancy, pregnancy-induced hypertension in mid- and late pregnancy, and abruptio placentae in late pregnancy, are relatively common, and recognition and management of them should be an integral part of the emergency physician’s knowledge base. The emergency physician must consider the signs and symptoms, week of gestation, and stability of the patient when developing management strategies.

Problems in Early Pregnancy

Miscarriage

Perspective

Spontaneous miscarriage is common in pregnancy. Early pregnancy loss (positive human chorionic gonadotropin [hCG] finding but less than 6 weeks after last normal menstrual period) occurs in approximately one fourth of pregnancies.\(^1\)\(^2\) The overall embryonic and fetal loss rate after implantation ranges up to one third of detectable pregnancies. The risk of miscarriage rises with increasing maternal age (fivefold increase in those older than 40 years compared with those 25–29 years), increasing paternal age, alcohol use, increased parity, low pre-pregnancy body mass index, maternal stress, and history of vaginal bleeding.\(^3\) Approximately 80% of miscarriages occur during the first trimester; the rest occur before 20 weeks of gestation. Fetal demise after 20 weeks of gestation or when the fetus is more than 500 g is considered premature birth.

Threatened or actual miscarriage is a common patient presentation in the emergency department (ED). Approximately one fourth of clinically pregnant patients experience some bleeding. It is widely estimated that approximately 50% of all women who have bleeding during early pregnancy miscarry, although the risk is probably higher in the ED population.\(^4\)\(^5\) Those with a history of bleeding who do not miscarry have otherwise fairly normal pregnancies, although they have approximately twice the risk of premature birth and low-birthweight infants.\(^6\)

Pathophysiology. The two major causes of miscarriage are uterine malformations and chromosomal abnormalities. In some cases, the ovum never develops (anembryonic gestation). In the majority of early miscarriages, fetal death precedes clinical miscarriage, often by several weeks. Although clinical symptoms of miscarriages are most common between 8 and 12 weeks of gestation, sonographic evidence in most cases demonstrates death before 8 weeks; if fetal viability can be demonstrated by heart activity and a normal sonogram, the subsequent fetal loss rate is only 3.4%.\(^7\)

Chromosomal abnormalities are associated with approximately 40% of miscarriages. Maternal factors that increase the risk of miscarriage include congenital anatomic defects, uterine scarring, leiomyomata, and cervical incompetence. Other conditions associated with increased miscarriage rates include toxins (e.g., alcohol, tobacco, and cocaine), autoimmune factors, endocrine disorders including luteal phase defects, and occasional maternal infections.\(^2\)

Terminology. Several stages of miscarriage are recognized. In threatened miscarriage, the patient has bleeding but a closed internal cervical os. The risk of miscarriage in this population is estimated at 35 to 50%, depending on patient demographics and severity of symptoms.\(^4\) If the internal cervical os is open, the miscarriage is considered inevitable. If products of conception (POCs) are present at the cervical os or in the vaginal canal, the miscarriage is termed incomplete. Completed miscarriage occurs when the uterus has expelled all fetal and placental material, the cervix is closed, and the uterus is contracted. Establishing the diagnosis of completed miscarriage is difficult in the ED unless a gestational sac is visualized because the cervix may close after an episode of heavy bleeding and clot passage without or after only partial expulsion of POCs. Unless an intact gestation is passed and recognized, completed miscarriage should be diagnosed only after a dilation and curettage (D&C) with pathologic confirmation of gestational products; a sonogram demonstrating an empty uterus with a prior known intrauterine pregnancy (IUP); or by reversion to a “negative” pregnancy test result, which may take up to several weeks.

Missed abortion is a relatively obsolete term referring to clinical failure of uterine growth over time. The terms anembryonic gestation (when no fetus is seen) and first- or second-trimester fetal
Clinical Features

Patient history should include the estimated length of the gestation; time since last menstrual period; symptoms of pregnancy (and loss of pregnancy symptoms); degree of bleeding; duration of bleeding; the presence of cramps, pain, or fever; and attempts by the patient to induce miscarriage. The severity of symptoms does not correlate well with the risk of miscarriage, although cramping and passage of clots are thought more likely to occur as the miscarriage becomes inevitable.

The assessment of the patient who experiences first-trimester vaginal bleeding includes a careful abdominal examination to evaluate for tenderness or peritoneal irritation from a potential ectopic pregnancy as well as to determine uterine size (the uterus should not be palpable abdominally). Pelvic examination should be performed to evaluate whether the cervix is closed or open, to look for clots or POCs, and to determine the degree of vaginal bleeding, as well as uterine size and tenderness. The cervix should be gently probed with a ring forceps (not a Q-Tip) to determine whether the internal os (1.5 cm deep to the external os) is open or closed. This is unnecessary in the patient who has a clearly open os or visible POCs but can be safely performed during the first trimester as long as the forceps are used gently and do not penetrate the cervix more than 2 or 3 cm. In the patient with second-trimester bleeding, probing should not be done because the uterus is more vascular and the organized placenta may overlie the cervical os. Parous females normally have an open or lax external os, a finding of no significance. The adnexa may be enlarged, often unilaterally, either because the corpus luteum is cystic or because the pregnancy is ectopic. Significant adnexal or uterine tenderness should always raise the possibility of an ectopic pregnancy. Much less commonly, pelvic infection can cause uterine and adnexal tenderness during early pregnancy.

Any tissue that is passed should be suspended in saline or tap water (or viewed under low-power microscopy) to differentiate sloughing endometrium and organized clot from chorionic villi, which form fronds and appear feathery in the saline suspension. Except in the rare instance of heterotopic pregnancy (combined intrauterine and ectopic pregnancies), this reliably excludes ectopic pregnancy. Passage of tissue called the decidual cast in ectopic pregnancy can easily be confused with intrauterine miscarriage if the physician does not confirm the absence of chorionic villi in the tissue.

Diagnostic Strategies

A hemoglobin determination is useful to provide a baseline measurement and to evaluate the degree of bleeding in females whose bleeding persists. In addition, an Rh (Rhesus) type should be obtained. Ultrasonography is the primary means of evaluating the health of the fetus as well as its location (Table 176-1). Because historical and clinical estimations of gestational age are often inaccurate, ultrasonography is useful to provide an accurate measure of fetal age and viability (Box 176-1).

In the stable patient with threatened miscarriage, observation over time may be sufficient to determine when intervention is needed, as long as ectopic pregnancy has been excluded. Serial quantitative hCG levels are used to assess the health of the fetus if sonographic findings are indeterminate or if the gestational age is less than 6 or 7 weeks. The sonographic “discriminatory zone” is defined as the quantitative hCG level at which a normally developing IUP should reliably be seen. This is considered to be 6500 mIU/mL for transabdominal ultrasonography and 3000 mIU/mL by transvaginal ultrasonography.\(^9\) Ultrasonography can be performed or repeated when hCG levels rise to 3000 mIU/mL. If hCG levels are flat or decline, or if sonographic criteria for fetal demise are demonstrated (see Box 176-1), the patient should be referred to an obstetrician for follow-up to be sure the miscarriage completes.

Differential Considerations

Of greatest concern is the possibility of ectopic pregnancy, which can masquerade as a threatened miscarriage in the early stages. Even in the patient with painless vaginal bleeding, the diagnosis of ectopic pregnancy must be considered. For this reason, early ultrasonography is imperative to locate the pregnancy in the patient who has bleeding or pain.

Other diagnoses should also be considered. A small amount of bleeding occurs at the time of implantation of the blastocyst into the endometrium and occasionally at the time of the first missed menses. Molar pregnancy is also characterized by vaginal bleeding, usually during the late first trimester or the second trimester. This condition can be identified by ultrasonography. Cervical and vaginal lesions can also cause local bleeding and can usually be seen on vaginal inspection.

Management

After assessment of hemodynamic status and management of blood loss, a patient with a threatened miscarriage requires very little specific medical treatment. Anti-D immunoglobulin should be administered if the patient is Rh-negative (unless the father is also known to be Rh-negative). A 50-µg dose is used during the first trimester and a full 300-µg dose after the

Factors for ectopic pregnancy are present or if the patient has ever had a miscarriage, and ultrasonography should be employed urgently if risk factors are present. In the patient who is planning pregnancy termination, prompt referral should be encouraged and chorionic villi confirmed at the time of uterine evacuation.

Unless an IUP is diagnosed, the patient with threatened miscarriage should be given careful instructions to return if she has signs of hemodynamic instability, significant pain, or other symptoms that might indicate ectopic pregnancy (so-called ectopic precautions). In conjunction with gynecologic colleagues, an ED protocol is useful to determine when follow-up sonographic evaluation and serial hCG measurements should be obtained. In addition, studies have indicated that low progesterone and low inhibin A levels can also be predictors of early pregnancy loss, although they are not in widespread use.

Fifty percent or more of women with threatened miscarriage who are seen in the ED ultimately miscarry. Treatment to “prevent” miscarriage is not useful because most fetuses can be shown to be nonviable 1 or 2 weeks before actual symptoms occur. In the vast majority of cases, spontaneous miscarriage is the body’s natural method of expelling an abnormal or undevolved (blighted) pregnancy. Thus, a major goal of early management should be patient education and support. Patients should be advised that moderate daily activities will not affect the pregnancy. Tampons, intercourse, and other activities that might induce uterine infection should be avoided as long as the patient is bleeding, and she should return immediately for fever, abdominal pain, or a significant increase in bleeding. Cramping from a known IUP can be safely treated with oral narcotics, if needed. If the patient passes tissue, it should be brought to a provider to examine for POCs because differentiation of fetal parts or villi from decidual slough or casts is difficult.

Patient counseling is paramount with threatened miscarriage. Determination of fetal viability can be helpful in either reassuring the mother or preparing her for probable fetal loss. Miscarriages are associated with a significant grieving process, which is frequently more difficult because early pregnancy is unannounced and early fetal death is not publicly recognized.

Because many women consider that small falls, injuries, or unannounced and early fetal death is not publicly recognized. Cramping from a known IUP can be safely treated with oral synthetic narcotics, if needed. If the patient passes tissue, it should be brought to a provider to examine for POCs because differentiation of fetal parts or villi from decidual slough or casts is difficult.

Patient counseling is paramount with threatened miscarriage. Determination of fetal viability can be helpful in either reassuring the mother or preparing her for probable fetal loss. Miscarriages are associated with a significant grieving process, which is frequently more difficult because early pregnancy is unannounced and early fetal death is not publicly recognized. Because many women consider that small falls, injuries, or stress during the first trimester can precipitate miscarriage, patients should be reassured that they have done nothing to cause miscarriage. It is important to make them aware that miscarriage is common, grieving is normal, and counseling may be beneficial. A follow-up appointment should be scheduled after miscarriage to support the patient in resolving such issues.

Treatment of the patient with inevitable miscarriage includes observation, dilation and evacuation, or D&C to remove the remaining intrauterine contents. When the miscarriage is incomplete, the uterus may be unable to contract adequately to limit bleeding from the implantation site. Bleeding may be brisk, and gentle removal of fetal tissue from the cervical os with ring forceps during the pelvic examination often slows bleeding considerably.

Management of patients with presumed completed spontaneous miscarriage is more complicated. If the patient brings tissue with her, this should be sent to the pathology department for evaluation. Unless an intact gestational sac or fetus is visualized, it is rarely clear clinically whether miscarriage is “complete.” Studies have shown that in women with a history consistent with miscarriage who have minimal remaining intrauterine tissue as determined by ultrasonography, expectant management is safe, but only if ectopic pregnancy can be excluded. If endometrial tissue is not seen with ultrasonography, bleeding is mild, and gestational age is less than 8 weeks, curettage is frequently unnecessary and the patient can be safely followed by a gynecologist for serial hormonal assays. Up to 80% of women with first-trimester miscarriage complete the miscarriage without intervention. However, the need for later visits and procedures may be decreased by uterine curettage, particularly if the fetal pole or a gestational sac is visible on the sonogram at the time of evaluation. Medical management with misoprostol instead of D&C is also an option and has a success rate of 84%. The patient should be instructed to return if uncontrolled bleeding, severe pain or cramping, fever, or tissue passage occurs. Follow-up is recommended in 1 or 2 weeks to ensure that the miscarriage is complete.

After miscarriage, the patient should be advised that fetal loss, even during the first trimester, can cause significant psychological stress. Follow-up in 1 or 2 weeks with a gynecologist should be provided. Some physicians prescribe antibiotics after D&C (usually doxycycline or metronidazole), particularly in patient populations at high risk for genital tract infections. Ergonovine or methylergonovine (0.2 mg PO twice daily) can be used to stimulate uterine involution. The patient should be advised to return if signs of infection (fever or uterine tenderness) occur, if bleeding resumes, or if further tissue is passed.

**Ectopic Pregnancy**

**Perspective**

Ectopic pregnancy, or pregnancy implanted outside the uterus, is an increasingly frequent problem that poses a major health risk to women during the childbearing years. It is the third leading cause of maternal death, responsible for 6% of maternal mortality. The incidence of ectopic pregnancy has risen steadily over several decades and now accounts for approximately 2% of all pregnancies. Although the incidence of ectopic pregnancy is highest in women age 25 to 34 years, the rate is highest among older women and women belonging to minority groups. Simultaneous intrauterine and extrauterine gestations (heterotopic pregnancy) have historically been rare, occurring in approximately 1 in 4000 pregnancies; more recently, women who have undergone assisted reproduction techniques with embryo transfer have demonstrated a risk of one of the pregnancies being ectopic of 4% or greater. The incidence of ectopic pregnancy among women presenting to the ED with vaginal bleeding or pain in the first trimester is consistently approximately 10% in several series.

**Principles of Disease**

Implantation of the fertilized ovum occurs approximately 8 or 9 days after ovulation. Risk factors for an abnormal site of implantation include prior tubal infection (50% of cases), anatomic abnormalities of the fallopian tubes, or abnormal endometrium (host factors). These result in failure of the embryo to implant in the endometrium. The risk of ectopic pregnancy increases approximately threefold after a patient has had pelvic inflammatory disease (PID). In recent studies, one fourth of patients with ectopic pregnancies have had tubal surgery, including tubal sterilization or removal of ectopic pregnancy. If the patient is currently using an intrauterine device,
increased risk can occur from complicating PID or from failure of the intrauterine device to prevent ectopic pregnancy as well as preventing endometrial implantation. All forms of contraception except intrauterine device use and tubal sterilization decrease the incidence of ectopic pregnancy. After an ectopic pregnancy, the risk of a subsequent ectopic pregnancy was 22% in one series of women trying to conceive again (Box 176-2).\textsuperscript{21}

When abnormal implantation occurs in the fallopian tubes, on the ovaries, or in the cervix, the pregnancy usually grows at a less than normal rate, which can result in abnormally low or declining hCG production. Leakage of blood occurs intermittently through the tubal wall or out the fimbrial ends, with spillage into the peritoneal cavity. Bleeding and other symptoms are usually intermittent. Three outcomes are possible: Tubal abortion may occur into the peritoneal cavity or vagina, spontaneous involution of the pregnancy may occur, or rupture of the pregnancy with internal or vaginal bleeding may result. Implantation in the uterine horn (cornual pregnancy) is particularly dangerous because the growing embryo can use the myometrial blood supply to grow larger (10–14 weeks of gestation) before rupture occurs.

**Clinical Features**

The classic clinical picture of ectopic pregnancy is a history of delayed menses followed by abdominal pain and vaginal bleeding in a patient with known risk factors. Unfortunately, this history is neither sensitive nor specific. Risk factors for ectopic pregnancy are absent in almost half of patients. Fifteen to 20% of patients with symptomatic ectopic pregnancy have not missed a menstrual period, and occasionally the patient has no history of vaginal bleeding. Abdominal pain is most commonly severe, peritoneal in nature, and constant. Shoulder pain implies free fluid in the peritoneal cavity and is very suggestive of an ectopic pregnancy with significant hemorrhage. The pain of ectopic pregnancy can also be crampy, intermittent, or even absent.\textsuperscript{1,22}

The physical examination findings in ectopic pregnancy are likewise variable. Vaginal bleeding, uterine or adnexal tenderness, or both in the patient with a positive pregnancy test result should trigger consideration for ectopic pregnancy. Tachycardia is not always present, even with significant hemoperitoneum; hemoglobin is usually normal and hypotension may be seen.\textsuperscript{25} The presence of peritoneal signs, cervical motion tenderness, or lateral or bilateral abdominal or pelvic tenderness indicates increased likelihood of an ectopic pregnancy. If significant peritoneal irritation is present, pain can preclude accurate bimanual examination. Adnexal masses are felt in only 10 to 20% of patients with ectopic pregnancy.\textsuperscript{3,22}

Vaginal bleeding is often mild. Heavy bleeding with clots or tissue usually suggests a threatened or incomplete miscarriage, although the patient with an ectopic pregnancy who has decreasing hormonal levels may experience endometrial sloughing, which can be mistaken for passage of fetal tissue. Passed tissue should be examined, as with cases of miscarriage, in tap water or saline (or under low-power microscopy). Unless fetal parts or chorionic villi are seen, ectopic pregnancy should not be excluded in the patient with bleeding or passage of “tissue.”

**Diagnostic Strategies**

Because both the history and the physical examination of the patient with ectopic pregnancy are insensitive and nonspecific, ancillary studies are required to locate the pregnancy in any patient who has abdominal pain or vaginal bleeding and a positive pregnancy test result. Technologic advances have allowed accurate detection or exclusion of ectopic pregnancy in the assessment of the woman with first-trimester vaginal bleeding or pelvic pain. Ultrasonography and hormonal assays are the most commonly used ancillary tests. In addition, laparoscopy can be the most efficient diagnostic tool in some instances.

**Ultrasonography.** Ultrasonography is the primary method used to locate early gestation, establish gestational age, and assess fetal viability. Transabdominal ultrasonography is most useful for identifying IUPs with fetal heart activity and excluding ectopic pregnancy (except in patients at high risk for heterotopic pregnancy due to infertility procedures).\textsuperscript{3} Transvaginal ultrasonography is more sensitive, recognizes IUP earlier than transabdominal ultrasonography, and is diagnostic in up to 80% of stable patients presenting in the first trimester.\textsuperscript{25} In general, an indeterminate ultrasound usually does not result in a diagnosis of normal pregnancy; one series of more than 1000 pelvic ultrasounds reported that 53% of indeterminate ultrasounds resulted in a diagnosis of embryo demise, 15% were ectopic pregnancies, and only 29% had an IUP.\textsuperscript{23} However, correlation of sonographic results with quantitative hCG measurements can add to the predictive value. With hCG less than 1000 mIU/mL, the risk of ectopic pregnancy increases fourfold; ultrasonography is still diagnostic in a significant minority of patients (one third of patients with ectopic pregnancy), although the accuracy of sonographic findings may decrease.\textsuperscript{19,24} Normal pregnancy is unlikely if no gestational sac is seen by transvaginal ultrasonography with an hCG level greater than 3000 mIU/mL, but the differential diagnosis includes both miscarriage and ectopic pregnancy.\textsuperscript{24} Unfortunately, levels of approximately 1500 mIU/mL develop in only approximately half of patients with ectopic pregnancies (see Table 176-1).\textsuperscript{1,9}

Indeterminate sonograms, which demonstrate neither an IUP nor extraterine findings suggestive of ectopic pregnancy (Box 176-3), occur in approximately 20% of ED evaluations of women with first-trimester bleeding or pain. Ectopic pregnancy is more likely among this subgroup with indeterminate sonograms if the hCG level is less than 1000 mIU/mL and when the uterus is empty. Endometrial debris and fluid in the uterus do not exclude ectopic pregnancy.\textsuperscript{27}

**Hormonal Assays.** The quantitative hCG levels have two primary uses in ED evaluation: Serial levels can be used in the stable patient who can be followed as an outpatient, and a single level can be correlated with sonographic results for improved interpretation. hCG levels normally double every 1.8 to 3 days for the first 6 or 7 weeks of pregnancy, beginning 8 or 9 days after ovulation. An initial quantitative level can be measured at the time of the ED visit, particularly if the sono-
**BOX 176-3**  
**SONOGRAPHIC FINDINGS IN THE PATIENT WITH SUSPECTED ECTOPIC PREGNANCY**

**Diagnostic of Intrauterine Pregnancy (IUP)**
- “Double” gestational sac
- Intrauterine fetal pole or yolk sac
- Intrauterine fetal heart activity

**Diagnostic of Ectopic Gestation**
- Pregnancy in fallopian tube (Fig. 176-1)
- Ectopic fetal heart activity (Fig. 176-2)
- Ectopic fetal pole

**Suggestive of Ectopic Gestation**
- Moderate or large cul-de-sac fluid without IUP
- Adnexal mass without IUP*

**Indeterminate**
- Empty uterus (Fig. 176-3)
- Nonspecific fluid collections (Fig. 176-4)
- Echogenic material
- Abnormal sac (Fig. 176-5)
- Single gestational sac

*Complex mass most suggestive of ectopic pregnancy, but cyst can also be seen with ectopic pregnancy.

gram is indeterminate or the gestational age is estimated as less than 6 weeks. A repeat level should be measured 48 to 72 hours later. Levels that fall or double slowly are associated with abnormal pregnancy, either intrauterine or ectopic. However, rising hCG levels can be seen during early ectopic pregnancy, with falling levels of hCG seen initially in only 40% of ectopic pregnancies. Twenty-one percent of women with an ectopic pregnancy in one series had an initial rise in hCG at a rate consistent with an IUP.26
Single quantitative hCG levels can also be useful in conjunction with ultrasonography; normal IUPs should be visible transvaginally at 3000 mIU/mL hCG (see Table 176-1). A benign course for ectopic pregnancy cannot be assumed with low hCG levels; ruptured ectopic pregnancies requiring surgery have been reported with very low or absent levels of hCG.27

Serum progesterone levels have been studied as an additional or alternative marker to determine which patients need further evaluation and follow-up for possible ectopic pregnancy. Progesterone rises earlier than hCG in normal pregnancy and plateaus with levels greater than 20 ng/mL, so measuring serial levels over time is not necessary. Levels less than 5 ng/mL exclude viable IUP (with rare exceptions) and could be useful when hCG levels are low, ultrasonography is indeterminate, and the clinician is considering D&C or laparoscopy. The ability of a progesterone level to differentiate ectopic pregnancy from a failed IUP is limited, however, and it is not a standard tool for evaluation.22

Other Ancillary Studies. Culdocentesis is not commonly used in stable patients with suspected ectopic pregnancy if ultrasonography is available. Culdocentesis is less sensitive and specific than ultrasonography for detecting hemoperitoneum, and several series report a nondiagnostic (i.e., dry) tap in approximately one fourth of patients.29 Culdocentesis could be considered, however, to verify hemoperitoneum in the unstable patient who cannot tolerate the time required for ultrasonography or when emergency transfer is being considered for gynecologic consultation and definitive care.

Dilation and evacuation can be used in patients without a viable IUP or ectopic pregnancy on ultrasonography to differentiate intrauterine miscarriage from ectopic pregnancy. Identification of chorionic villi in endometrial samples is seen in approximately 70% of patients and excludes ectopic pregnancy (except in infertility patients). Identification of chorionic villi can be made even in 50% of women with an empty uterus on ultrasonography and limits the need for laparoscopy to exclude ectopic pregnancy in this population.30

Although invasive, laparoscopy is extremely accurate as a diagnostic (and therapeutic) procedure for possible ectopic pregnancy. It is the diagnostic treatment of choice in the unstable first-trimester patient with frank peritoneal signs and is also indicated in patients with significant peritoneal fluid or an ectopic gestation in the pelvic cavity. Medical alternatives for management of ectopic pregnancy have resulted in decreased indications in stable patients.31

**Differential Considerations.** The spectrum of clinical presentations in ectopic pregnancy is wide, so the differential diagnosis includes essentially all first-trimester complications. Threatened miscarriage, the most common alternative diagnosis, can be recognized by sonographic evidence of an IUP, either healthy or failed. Hypovolemia may be seen, particularly in incomplete miscarriage, but hypotension without significant vaginal hemorrhage is highly suggestive of ectopic pregnancy. Identification of fetal parts or chorionic villi in tissue expelled or obtained during D&C is useful to confirm a complication of IUP, although this is not sufficient to exclude ectopic pregnancy in the patient who has received infertility treatment and has an increased risk of heterotopic gestation.

A ruptured corpus luteum cyst should also be considered in the patient who has first-trimester bleeding associated with peritoneal pain or irritation. The corpus luteum normally supports the pregnancy during the first 7 or 8 weeks. Rupture causes pelvic pain and peritoneal irritation. Ultrasonography is helpful if it reveals an IUP (except in patients with in vitro fertilization). During early gestation, when ultrasonography is nondiagnostic, free fluid is usually visible by ultrasonography and serial observation may be required. If the patient is unstable (especially if an IUP cannot be identified by ultrasonography), laparoscopy or, rarely, laparotomy may be required to differentiate between the two conditions.

**Management**

Classically, approximately 20% of women with ectopic pregnancies manifest signs and symptoms warranting immediate intervention.32 This includes patients with significant hypovolemia, large amounts of peritoneal fluid, or an open cervical os. For patients with significant signs of hypovolemia, rapid volume resuscitation should be instituted with intravenous fluids and blood products as necessary, and a baseline hemoglobin level and type and crossmatch should be obtained. A D&C or evacuation procedure with examination of endometrial contents for products of conception can be performed urgently in the unstable patient with an open cervical os.

If the patient remains unstable, immediate surgery is warranted. Laparoscopy may be indicated for patients who stabilize with treatment or for those who are hemodynamically stable but exhibit significant peritoneal signs. One study reported that identifying free fluid in Morrison’s pouch on bedside ultrasonography predicted the need for operative intervention in the majority of cases in patients with suspected ectopic pregnancies.33 All patients with ectopic pregnancy who are Rh-negative should be given Rh immunoglobulin 50 µg intramuscularly, unless the father is known to be Rh-negative.

The majority of patients who seek treatment for bleeding or pain during the first trimester of pregnancy are stable. In such patients, the goal should be to exclude ectopic pregnancy in a timely manner. In the patient with significant pain by history or examination, or significant risk factors for ectopic pregnancy, ultrasonography should be performed before discharge. If the results are indeterminate, a quantitative hCG may be helpful in determining the patient’s risk for ectopic pregnancy.

In low-risk patients with only minor symptoms or bleeding, ectopic pregnancy is still a possibility. Two general outpatient approaches can be considered. In most institutions, ultrasonography is the initial screening tool (Fig. 176-6), performed by the emergency medical team or by radiology personnel. If an IUP is not seen, quantitative hCG levels help stratify patients by risk. Cost, availability, and convenience will drive the ordering of ancillary studies in different institutions. In all
cases, if the patient is discharged, careful instructions are given for symptoms that would require her earlier return (ectopic precautions).

An alternative strategy using hCG first has also been used. However, waiting times for the serum assay can increase length of stay in the ED. In addition, ultrasonography is usually diagnostic of IUP or ectopic pregnancy, even if the hCG level is less than 1000 mIU/mL.\(^\text{18,23}\) In most hands, the initial sonogram provides more rapid and accurate information at the time of an ED visit.

A significant minority of patients have indeterminate sonographic results and hCG levels less than 1500 mIU/mL. When the hCG levels never rise to the discriminatory zone, the differential diagnosis includes intrauterine fetal demise and ectopic pregnancy. Early D&C with identification of POCs can be useful to the patient with nonrising hCG levels to strongly suggest ectopic pregnancy.\(^\text{30}\) Alternatively, hCG levels can be followed until they reach zero, particularly if initial levels are low.

Although laparotomy may be required for emergency patients who have ectopic pregnancies, an increasing number of surgeries are being performed through the laparoscope. Salpingostomy is preferred to salpingectomy if the patient is stable and the procedure is technically feasible. Overall, the advent of transvaginal ultrasonography has resulted in a decreased number of surgeries and a trend toward nonoperative management.\(^\text{35}\)

Medical management has become standard in many areas for the stable patient with minimal symptoms and is cost-effective when considering subsequent fertility.\(^\text{31}\) Methotrexate is the drug most commonly used to treat early ectopic pregnancy. It causes destruction of rapidly dividing fetal cells and involution of the pregnancy. Medical treatment is most often used for patients with a tubal mass less than 4 cm in diameter, no fetal cardiac activity, and no sonographic evidence of rupture. Although there is no agreed upon cutoff for single-dose methotrexate, a systematic review found that patients with an hCG of greater than 5000 mIU/mL had an increased failure rate.\(^\text{32}\) Medical therapies are associated with an 85 to 93% success rate, with no significant difference between single- and multiple-dose protocols.\(^\text{35,36}\) Pelvic pain is common (60%) in patients receiving methotrexate, even when used successfully.\(^\text{37}\) Indications of methotrexate failure and need for rescue surgery include decreasing hemoglobin levels, significant pelvic fluid, or unstable vital signs. All patients receiving methotrexate require close follow-up until the hCG level reaches zero, which may take 2 or 3 months.

### Molar Pregnancy

Gestational trophoblastic disease (molar pregnancy) comprises a spectrum of diseases characterized by disordered proliferation of chorionic villi. In the absence of fetal tissue, the pregnancy is termed a complete hydatidiform mole. More rarely, if fetal tissue is present and trophoblastic hyperplasia is focal, it is called an incomplete mole. In approximately 19% of molar pregnancies, neoplastic gestational disease develops, with persistence of molar tissue after the pregnancy has been evacuated.\(^\text{38}\) Metastatic disease can develop, requiring chemotherapy and intensive oncologic management.

Early molar pregnancy is usually not clinically apparent. Many patients present with abdominal pain, nausea and vomiting, or vaginal bleeding, and it may be difficult to differentiate these patients from those with threatened miscarriage or ectopic pregnancy by historical features alone.\(^\text{39}\) Patients sometimes seek treatment for apparent persistent hyperemesis gravidarum from high circulating levels of hCG, bleeding or intermittent bloody discharge or failure to hear fetal heart tones during the second trimester is the usual initial clue to diagnosis. If molar pregnancy spontaneously aborts, it is usually in the second trimester (before 20 weeks), and the patient or physician may note passage of grapelike hydatid vesicles. Uterine size is larger than expected by date (by more than 4 weeks) in approximately 30 to 40% of patients. Theca lutein cysts may be present on the ovaries as a result of excessive hormonal stimulation, and torsion of affected ovaries can be seen.

The diagnosis of hydatidiform mole is based on the characteristic sonographic appearance of hydropic vesicles within the uterus, described as a “snowstorm” appearance (Fig. 176-7). Alternatively, cystic changes are seen in partial molar pregnancies. In some cases, partial molar pregnancy is detected only on pathologic examination of abortion specimens.\(^\text{40}\) Complications of molar pregnancy include preeclampsia or eclampsia (which can develop before 24 weeks of gestation); pulmonary embolization of trophoblastic cells; hyperemesis gravidarum; and significant uterine bleeding, either acute or chronic. Ultrasonography usually provides the diagnosis of complete molar pregnancy, either in the second-trimester patient who has “threatened miscarriage” or during sonographic assessment for fetal well-being and size. However, ultrasonography is only 58% sensitive, and diagnosis of partial mole is made in 17% of cases.\(^\text{40}\) Up to two thirds of molar pregnancies are diagnosed by pathologic specimens after miscarriage.\(^\text{40}\)

### COMPLICATIONS OF LATE PREGNANCY

#### Vaginal Bleeding in Later Pregnancy

**Perspective**

Bleeding during the second half of pregnancy occurs in approximately 4% of pregnancies. Only 20% of miscarriages
Management is supportive and expectant because fetal rescue is impossible at this level of fetal immaturity. In the third trimester, vaginal bleeding is still associated with significant morbidity in approximately one third of women, but the treatment includes consideration of urgent delivery.41

Abruptio Placentae

Principles of Disease. Abruptio placentae, or separation of the placenta from the uterine wall, is believed to account for approximately 30% of episodes of bleeding during the second half of pregnancy. In addition, small subclinical or marginal separations may go undetected until the placenta is examined at delivery and probably account for many of the other self-limited episodes of bleeding for which no diagnosis is made. In cases of nontraumatic abruptio placentae, apparently spontaneous hemorrhage into the decidua basalis occurs, causing separation and compression of the adjacent placenta. Small amounts of bleeding may be asymptomatic and remain undetected until delivery. In other instances, the hematoma expands and extends the dissection; bleeding may be concealed or may be clinically apparent if dissection occurs along the uterine wall and through the cervix. Placental separation can be acute or can be an indolent problem throughout late pregnancy.

Abruptio placentae is most clearly associated with maternal hypertension and preeclampsia; it is also more common with increasing maternal age and parity, a history of smoking, thrombophilia, prior miscarriage, prior abruptio placentae, and cocaine use.41,42 Placental separation can also be associated with blunt trauma to the abdomen. In such instances, the cause appears to be shearing of a nonelastic placenta from the easily distorted elastic uterine wall at the time of traumatic impact. Women who reported physical violence during pregnancy were twice as likely to have an abruption than women who did not report any violence.43

Clinical Features. Vaginal bleeding occurs in 70% of patients with abruptio placentae.43 Blood is characteristically dark and the amount is often insignificant, although the mother may have hemodynamic evidence of significant blood loss. Uterine tenderness or pain is seen in approximately two thirds of women; uterine irritability or contractions are seen in one third. With significant placental separation, fetal distress occurs and the maternal coagulation cascade may be triggered, causing disseminated intravascular coagulation.41

There is a wide spectrum of severity of symptoms and risk in placental separation. Up to 20% of women will have no pain or vaginal bleeding.42 Assessment is generally based on clinical features, coagulation parameters, and signs of fetal distress. Slight vaginal bleeding, little or no uterine irritability, the absence of signs of fetal distress, and normal coagulation characterize mild abruption. As the separation becomes more extensive, it is associated with more vaginal bleeding (or hidden maternal blood loss), increased uterine irritability with or without tetanic contractions, declining fibrinogen levels, and evidence of fetal distress and maternal tachycardia. In cases of severe abruptio placentae (15% of cases), the uterus is tetanically contracted and very painful, maternal hypotension results from visible or concealed uterine blood loss, fibrinogen levels are less than 150 mg/dL, and fetal death can occur. Ultrasonography is insensitive in the diagnosis of abruptio placentae, often because the echogenicity of fresh blood is so similar to that of the placenta. Symptomatic or even fetus-threatening abruption can occur in the presence of a negative sonogram.44

Fetal distress and death occur in approximately 15% of patients with abruptio placentae due to interruption of placental blood and oxygen flow. Risk of fetal death increases in

Figure 176-7. Ultrasound showing molar pregnancy. (Courtesy of Mary Ann Edens, MD.)

occur after the first trimester, and the most important differential diagnoses after 12 to 14 weeks of gestation are abruptio placentae and placenta previa. Often, the cause is not determined, although occult marginal placental separations (which can be recognized only by placental inspection at delivery) are held to be a common source of bleeding from above the cervix. Other causes of late vaginal bleeding include early labor, various cervical and vaginal lesions, lower genital tract infections, and hemorrhoids.

Bleeding during the second trimester before the fetus is potentially viable (14–24 weeks) is not benign. One third of fetuses are ultimately lost when maternal bleeding occurs.
proportion to both the percentage of placental surface involved and the rapidity of separation. Fetal distress may result from the loss of placental blood flow, associated maternal hemorrhage (into the uterine cavity or externally), increased uterine tone, or resultant disseminated intravascular coagulation. Maternal death can result, usually from coagulopathy or exsanguination. Fetomaternal transfusion occurs in a significant minority of patients. Placental separation also predisposes the mother to amniotic fluid embolism.

**Differential Considerations.** The main alternative diagnosis in the woman with late-pregnancy bleeding is placenta previa, which is usually associated with painless, bright red bleeding and must be excluded with ultrasonography. Lower genital tract or rectal lesions and bloody show (blood-tinged cervical mucous plug) are also considerations.

In the patient with abdominal pain but no vaginal bleeding, abruptio placentae with concealed hemorrhage must be distinguished from other causes of abdominal pain in later pregnancy: complications of preeclampsia, pyelonephritis, various liver diseases, gallbladder disease, appendicitis, and ovarian torsion. Uterine irritability caused by abruptio placenta can also be confused with early labor; in one series, almost one fourth of patients were misdiagnosed as having premature labor until fetal distress occurred. If the patient has acute catastrophic hypotension, anamniotic fluid embolus (with or without abruptio placentae) and uterine rupture must be considered.41

**Placenta Previa**

**Principles of Disease.** Placenta previa, or implantation of the placenta over the cervical os, is the other major cause of bleeding episodes during the second half of pregnancy. The risk of placenta previa is increased with maternal age, multiparity, smoking, and prior cesarean section.44 Bleeding occurs when marginal placental vessels implanted in the lower uterine segment are torn, either as the lower uterine wall elongates or with cervical dilation near the time of delivery. Early bleeding episodes tend to be self-limited unless separation of the placental margin is aggravated by iatrogenic cervical probing or onset of labor.

**Clinical Features.** Painless, fresh vaginal bleeding is the most common symptom of placenta previa. In approximately 20% of cases, some degree of uterine irritability is present, but this is usually minor. Vaginal examination usually reveals bright blood from the cervical os. Digital or instrumental probing of the cervix should never be done during the second half of pregnancy because it can precipitate severe hemorrhage in the patient with an asymptomatic or minimally symptomatic placenta previa. In the ED, speculum examination of the vagina and cervix should be performed only in those settings in which obstetric consultation is not readily available. It should be limited to an atraumatic partial speculum insertion to identify whether the bleeding is coming from the cervical os (and a presumed placenta previa), hemorrhoids, or a vaginal lesion that might not require urgent management.

Most cases of placenta previa identified during the midtrimester resolve by the time of delivery as the lower uterine segment elongates and the placenta no longer overlaps the cervical os. Central or total previa (which occurs in approximately 20% of cases) can, however, cause severe hemorrhage, with risk of exsanguination for the fetus and mother.

**Diagnostic Strategies.** Ultrasonography is the diagnostic procedure of choice for localizing the placenta and diagnosing placenta previa. Accuracy is excellent; visualization of the placenta as well as the internal cervical os is required. The bladder should be emptied prior to examination for suspected placenta previa to avoid overdiagnosis of placenta previa. Transvaginal ultrasonography is safe and even more accurate for visualizing the relationships between the placenta and the internal os.45

**Management**

Patients who experience vaginal bleeding during late pregnancy should have immediate obstetric consultation and arrangements for safe transfer to an appropriate obstetric facility. Initial management consists of maternal stabilization, with establishment of two large-bore intravenous lines and fluid resuscitation, as well as continuous fetal monitoring if available. A baseline hemoglobin level should be obtained, and blood should be sent for type and crossmatch; baseline coagulation studies including platelet count, prothrombin time, and partial thromboplastin time should be performed; and fibrinogen level and the presence of fibrin split products should be determined. The normal fibrinogen level in pregnancy is 400 to 450 mg/dL; values below 300 mg/dL indicate significant consumption of coagulation factors.

Blood loss requiring transfusion can occur in patients with placenta previa or abruptio placentae. Fresh frozen plasma or fresh whole blood may be needed because of the coagulopathy associated with significant abruptio placentae. Fetomaternal hemorrhage can occur with abruption. If the Rh-negative patient has not yet received her routine Rh immunoglobulin prophylaxis at 28 weeks, 300 μg of Rh immune globulin should be administered within 72 hours (unless the father is known to be Rh-negative).36 Transfer to the obstetric unit should be expedited if the patient is stable, or it should be done after initiation of resuscitation if she is unstable. If transfer to another hospital is required, a high-risk transfer team should be used if bleeding is significant or if the fetus is in distress. Although the bleeding source may not be identified or may be relatively benign, assessment is best accomplished by obstetricians who are accustomed to evaluating late-pregnancy complications and who can perform emergent cesarean section if needed.

In the obstetrics unit, fetal monitoring is continued. Ultrasonography is used primarily to locate the placenta and diagnose placenta previa; it may not be reliable in confirming the diagnosis of abruptio placentae. Occasionally, subplacental hemorrhages of abruptio placentae can be seen and changes in size of the collection can be monitored. If evidence of placenta previa is absent or equivocal, vaginal examination is performed in the delivery suite, where emergency cesarean section can be performed if uncontrolled bleeding is encountered.

Patients who have significant abruptio placentae may require early delivery (either vaginal or surgical, depending on fetal status). If placenta previa is diagnosed or if abruptio placentae is considered mild, the patient is admitted for close monitoring. The goal is to support the patient, ideally until fetal maturity is demonstrated and a successful delivery can be accomplished.

**Pregnancy-Induced Hypertension**

(Preeclampsia and Eclampsia)

**Perspective**

Hypertension is observed in approximately 6 to 8% of pregnancies and is generally divided into several categories.47 Gestational hypertension occurs during pregnancy, resolves during the postpartum period, and is recognized by a new blood pressure reading of 140/90 mm Hg or higher. Preeclampsia is gestational hypertension with proteinuria (>300 mg/24 hours), and eclampsia is the occurrence of seizures in the patient with
signs of preeclampsia. Progression of preeclampsia to eclampsia is unpredictable and can occur rapidly. Pregnancy-aggravated hypertension is chronic hypertension with superimposed preeclampsia or eclampsia. Chronic or coincidental hypertension is present before pregnancy or persists more than 6 weeks postpartum.42

Approximately 2 to 7% of pregnancies are complicated by pregnancy-induced hypertension. The incidence of actual eclampsia has progressively declined, but it is still one of the major causes of maternal mortality. The risk of pregnancy-induced hypertension is greatest in women younger than 20 years; primigravidas; those with twin or molar pregnancies; those with hypercholesterolemia, gestational diabetes, or obesity; and those with a family history of pregnancy-induced hypertension.48

Principles of Disease

Gestational hypertension/preeclampsia is a vasospastic disease of unknown cause unique to pregnant women. Vasospasm, ischemia, and thrombosis associated with preeclamptic changes cause injury to maternal organs, placental infarction and abortion, and fetal death from hypoxia and prematurity. The cause of eclampsia is not known, but recent research has centered on vascular responsiveness to endogenous vasopressors in the preeclamptic woman. Vascular responsiveness is normally depressed during pregnancy, which is a high-output, low-resistance state. Gestational hypertension is characterized by an even greater elevation in cardiac output, followed by an abnormally high peripheral resistance as the disease develops clinical manifestations. In patients with preeclampsia, the cardiac output eventually drops as peripheral resistance rises.49

The cause of these changes is not known, but endothelial dysfunction is purported to release vasoactive mediators and result in vasoconstriction.50 Antiplatelet agents during pregnancy have been reported to reduce the risk of development of preeclampsia, supporting the premise of an imbalance between levels of thromboxane and prostacyclin in preeclampsia.51

The vasospastic effects of gestational hypertension/preeclampsia are protean. Intravascular volume is lower than in normal pregnancy, central venous pressures are normal, and capillary wedge pressures are variable. Liver effects are believed to be due to hepatocellular necrosis and edema resulting from vasospasm. Renal injury causes proteinuria and may result in decreased glomerular filtration. Microangiopathic hemolysis may result from vasospasm, causing thrombocytopenia. Central nervous system effects include microvascular thrombosis and hemorrhage, as well as focal edema and hyperemia.48

Clinical Features

Signs and Symptoms. The patient with gestational hypertension has mild systolic or diastolic blood pressure elevation, no proteinuria, and no evidence of organ damage. Mental status assessment, testing of reflexes, abdominal examination, liver function studies, and coagulation studies should all yield normal results. Preeclampsia is associated with kidney changes and, in severe cases, other end-organ symptoms. Edema is often difficult to assess because pregnancy is normally associated with excess extracellular fluid and dependent edema, and it is no longer used as a criterion for recognizing preeclampsia. Proteinuria (>300 mg/24 hours) is variable at any given time and may not be detectable in a random urine specimen.51

In cases of severe preeclampsia, diastolic blood pressure can exceed 110 mm Hg, proteinuria is more severe, and there is evidence of vasospastic effects in various end organs. Central nervous system effects commonly include headache or visual disturbances. Thrombocytopenia may be present, liver function test findings may be elevated, and the liver is often tender. Renal dysfunction may be indicated by oliguria and elevated creatinine levels in addition to proteinuria.

Complications. The HELLP syndrome is a particularly severe form of preeclampsia that develops in 5 to 10% of women who have preeclamptic symptoms and is characterized by hemolysis, elevated liver enzymes, and low platelet count (<100,000/mL). Prothrombin time, partial thromboplastin time, and fibrinogen level are all normal, and blood studies reveal microangiopathic hemolytic anemia. Other complications of preeclampsia include spontaneous hepatic and splenic hemorrhage and abruptio placenta.

The most dangerous complication is eclampsia, which is the occurrence of seizures or coma in the setting of signs and symptoms of preeclampsia. Warning signs for development of frank eclampsia include headache, nausea and vomiting, and visual disturbances.52 Elevated total leukocyte count, creatinine, and aspartate aminotransferase are also predictive of increased morbidity for the patient with severe preeclampsia.53 Particularly in early eclampsia before 32 weeks of gestation, seizures may develop abruptly and hypertension may not be associated with edema or proteinuria.54 One third of eclamptic seizures occur after delivery, usually during the first 48 hours but occasionally as many as 28 days after delivery.55 After 48 hours postpartum and without predelivery signs of preeclampsia, other diagnoses such as intracranial hemorrhage should be considered. Maternal complications of eclampsia include permanent central nervous system damage from recurrent seizures or intracranial bleeding, renal insufficiency, and death.

The maternal mortality rate from eclampsia has been reduced with modern management and is currently less than 1%. Perinatal mortality has also decreased, although it remains 4 to 8%.56 Causes of neonatal death include placental infarcts, intrauterine growth retardation, and abruptio placenta. In addition, fetal hypoxia from maternal seizures and the complications of premature delivery mandated by the maternal condition contribute significantly to fetal mortality and morbidity.

Diagnostic Strategies

The patient who has severe preeclampsia should have an intravenous line and fetal monitoring initiated in a quiet but closely observed area. Blood testing should include complete blood cell count, renal function studies, liver function tests, platelet count, and coagulation profile. A baseline magnesium level should also be obtained. In the patient with actual seizures, serum glucose should be tested. If a history of preeclampsia is not obtained or the symptoms are refractory to magnesium sulfate therapy, a computed tomography (CT) scan of the head should be performed to exclude cerebral venous thrombosis or an intracranial bleed, either of which can occur in pregnancy (with or without pregnancy-induced hypertension) and may require specific treatment. CT scan abnormalities can be seen in half of patients with eclampsia. Patchy hemorrhage and microinfarcts of the cortex are characteristic and may be due to loss of cerebral autoregulation in patients with severe pregnancy-related hypertension. Diffuse cerebral edema can also be seen.56

Differential Considerations

Peripheral edema is common in normal pregnancy, and it may be difficult to differentiate normal edema from that of early preeclampsia. Differentiation of gestational hypertension from
preexistent hypertension is often impossible if no record of normal blood pressure is available. Seizures during pregnancy may be due to epilepsy as well as to other intracranial catastrophes, such as thrombosis or hemorrhage.

Management

In the patient who has mild preeclampsia, appropriate management includes documentation of blood pressure and reflexes, weight, and testing to ensure normal end-organ function. Accurate determination of gestational age by ultrasonography is needed to allow optimal management if symptoms progress. Limitation of physical activities (including bedrest) is the only demonstrated means of reducing blood pressure and allowing the pregnancy to be sustained longer. Definitive treatment is delivery of the fetus. Arrangement for close follow-up is important for patients who are not hospitalized.

Hospitalization is usually required for patients with sustained hypertension above 140/90 mm Hg and signs of severe preeclampsia. Baseline laboratory studies to identify end-organ effects in the liver, kidney, and hematologic systems should be obtained. Both diuresis and antihypertensive therapy have been remarkably unsuccessful in improving fetal outcome or prolonging pregnancy. Admission does, however, allow the obstetrician to accurately assess fetal age and well-being, maternal organ function, and the effect of bedrest on blood pressure before deciding the optimal timing of delivery.

Fulminant or severe preeclampsia, with marked blood pressure elevation (>160/110 mm Hg), associated with epigastric or liver tenderness, visual disturbance, or severe headache, is managed in the same way as eclampsia (Box 176-4). The goal is prevention of seizures and permanent damage to maternal organs. Magnesium sulfate is given for seizure prophylaxis.

Seizures and coma are the hallmarks of eclampsia, the ultimate consequence of preeclampsia. As in all seizure patients, hypoglycemia, drug overdose, and other causes of seizures should be excluded with appropriate tests. Eclamptic seizures are controlled in almost all patients by adequate doses of magnesium sulfate, although the mechanism of action remains elusive. Magnesium has little anti hypertensive effect but is the most effective anticonvulsant, preventing recurrent seizures while maintaining uterine and fetal blood flow. The goal of magnesium sulfate therapy is to terminate ongoing seizures and prevent further seizures. A loading dose of 6 g IV magnesium, followed by 2 g IV/hr, is recommended. Magnesium administration should be accompanied by clinical observation for loss of reflexes (which occurs at approximately 10 mg/dL) or respiratory depression (which occurs at levels >12 mg/dL, although actual serum magnesium levels are rarely monitored). The infusion should be stopped if signs of hypermagnesemia are seen; such patients may require assisted ventilation. Calcium gluconate, 1 g given slowly into a secure vein, will reverse the adverse effects of hypermagnesemia.

Despite ongoing controversy, the familiarity, physiologic advantages to the fetus, wide margin of safety, and high success rate in controlling seizures make magnesium sulfate the first-line drug in patients with eclampsia. Several reports highlight an international consensus that magnesium sulfate is more effective than nimodipine, phentoyin, or diazepam for prophylaxis against or treatment of eclamptic seizures. If seizures persist after the recommended doses of magnesium sulfate have been administered, further therapy should be given in conjunction with obstetric consultation and a careful search for other causes of seizures (e.g., hypoglycemia and intracranial bleed) should be instituted.

Although magnesium sulfate is not a direct antihypertensive, the hypertension associated with eclampsia is often controlled adequately by stopping the seizures. Rapid lowering of blood pressure can result in uterine hypoperfusion, so specific antihypertensive treatment is initiated only if the diastolic blood pressure remains above 105 mm Hg after control of seizures. Many patients do not require specific antihypertensive treatment after treatment with magnesium sulfate. The antihypertensive used most often by obstetricians is hydralazine. The dose is 5 mg IV, with repeated doses of 5 to 10 mg IV every 20 minutes as needed to keep the diastolic blood pressure below 105 mm Hg. Nimodipine and labetalol have also been reported to be safe and effective, although they are less widely used. Other antihypertensive agents are not well studied in this population because there are specific risks to uncontrolled lowering of blood pressure and loss of uteroplacental blood flow.

Although total body water in the eclamptic patient is excessive, intravascular volume is contracted and the eclamptic patient is very sensitive to further volume changes. Hypovolemia results in decreased uterine perfusion. Thus, diuretics and hyperosmotic agents should be avoided in patients with eclampsia. Although intravascular volume expansion in the face of volume contraction, increased systemic resistance, and vasospasm would seem reasonable, invasive monitoring has demonstrated that vasospasm is not reversed with intravenous fluid administration. Rather, excessive intravenous fluids increase extravascular fluid stores that are difficult to mobilize postpartum, resulting in a higher incidence of pulmonary edema in patients treated aggressively with fluid therapy. Invasive pulmonary artery pressure monitoring may be required for accurate fluid management in the eclamptic patient.

Amniotic Fluid Embolus

**Perspective**

Amniotic fluid embolus (AFE) is the release of amniotic fluid into the maternal circulation during intense uterine contractions or uterine manipulation or at areas of placental separation from the uterus decidua basalis (abruptio placentae), triggering a rapidly fatal anaphylactoid-type maternal response. Although AFE most commonly occurs during labor, in which

---

**BOX 176-4 MANAGEMENT OF ECLAMPSIA AND SEVERE PREECLAMPSIA**

- Control seizures with magnesium sulfate.
- Control hypertension after seizure control if diastolic blood pressure >105 mm Hg.
- Draw initial laboratory studies to assess organ injury: Complete blood count and platelet count
  - Liver function tests
  - BUN, creatinine
- Monitor urine output: maintain at <25 mL/hr.
- Limit intravenous fluid administration unless significant losses occur.
- Avoid diuretics and hyperosmotic agents.
- Perform a CT scan of head if consciousness is decreased or seizures persist, lateralizing signs are present, or there are other concerns.
- Initiate steps to delivery.

BUN, blood urea nitrogen; CT, computed tomography.

circumstance the maternal mortality rate is 25% or higher, it can also occur after induced abortions and miscarriages and spontaneously during the second and third trimesters. AFE can also occur after amniocentesis or in association with abruptio placentae after abdominal trauma. Although it is a rare syndrome, AFE is responsible for 13 to 30% of maternal deaths and is the fifth leading cause of direct maternal death.

Clinical Features

Amniotic fluid embolus should be suspected during the second or third trimester of pregnancy, particularly in the setting of uterine manipulation or contraction, when a patient experiences sudden hypotension, hypoxia, and coagulopathy. The embolization of amniotic fluid and the particulate matter suspended in it triggers a profound immunologic response when it enters the maternal circulation. Half of the cases of mortality occur during the first 2 hours when vasospasm, release of vaso-active substances, and mechanical plugging of vessels, particularly in the maternal pulmonary vascular tree, trigger abrupt cardiopulmonary collapse. In survivors, disseminated intra-vascular coagulation, acute respiratory distress syndrome, and left ventricular dysfunction develop. An initial seizure is seen in approximately 10% of patients. Bleeding diathesis may be the initial sign in some women.

Diagnostic Strategies

When AFE is suggested, a complete blood cell count, coagulation studies, arterial blood gases, and chest radiograph should be obtained. Urinary output should be monitored after urinary catheter placement. The diagnosis is usually made with certainty only at autopsy, with the finding of fetal hairs, squamous cells, and debris in the maternal circulation. Because squamous epithelial cells can be seen normally in the maternal pulmonary circulation, the typical clinical syndrome is also required for diagnosis.

Differential Considerations

Catastrophic pulmonary embolus, drug-induced anaphylaxis, and septic shock must be considered in the differential diagnosis. Seizure occurs in patients with eclampsia, but in that condition hypertension, rather than cardiovascular collapse, should be observed. Coagulopathy may be seen in patients with preeclampsia (HELLP syndrome), abruptio placentae, or other chronic coagulopathies seen in the nonpregnant patient.

Management

Amniotic fluid embolus is uncommon, so treatment is mainly anecdotal and based on animal studies. The most helpful modalities appear to be high-flow oxygen, support of ventilation and oxygenation with intubation, aggressive fluid resuscitation, inotropic cardiovascular support, and anticipation and management of consumptive coagulopathy. A few reports have indicated that plasma exchange may be helpful to remove triggering cytokines. Adequate management usually requires invasive hemodynamic monitoring in an intensive care unit.

Rh (Anti-D) Immunization in Pregnancy

Rh immunization occurs when an Rh-negative woman is exposed to Rh-positive fetal blood. Small numbers of fetal cells enter the maternal circulation spontaneously throughout pregnancy, but the maternal immune system is only triggered by significant loads of fetal cells, which can occur during the third trimester and at delivery. Sensitization occurs in up to 15% of Rh-negative women carrying Rh-positive fetuses. To prevent this, anti-D immunoglobulin (RhoGAM) is routinely administered to Rh-negative mothers (if the father is Rh-positive or his status is unknown) at approximately the 28th week of gestation to protect the mother from spontaneous sensitization, which occurs during the third trimester. Transplacental hemorrhage can also occur during uterine manipulation, threatened miscarriage (even without fetal loss), spontaneous miscarriage, surgery for ectopic pregnancy, and amniocentesis, although the risk is not clear. Anti-D immunoglobulin should be administered when these events occur. A dose of 50 µg can be used if the patient is at less than 12 weeks of gestation, although many pharmacies only carry the 300-µg dose, which can also be given. After 12 weeks, a 300-µg dose should be given. The half-life of immunoglobulin is 24 days, and it needs to be administered within 72 hours of a sensitization event to prevent antibody development.

The Kleihauer-Betke test of maternal blood has been used to detect fetal cells in the maternal circulation. Unfortunately, the test is difficult to perform, not immediately available in most emergency laboratories, and only sensitive enough to detect 5 mL of fetal cells in the maternal circulation. Because only 0.1 mL of fetal cells is required to sensitize the mother, routine immunoglobulin administration has been recommended in situations likely to result in sensitization. Patients with third-trimester bleeding are not at increased risk of sensitization compared with patients with normal pregnancy; RhoGAM should be administered only if the patient did not receive her prophylactic dose at 28 weeks. In instances of significant blunt trauma to the uterus, the Kleihauer-Betke test should be ordered to detect the rare large fetal transfusions that may require specific fetal blood therapy or administration of additional immunoglobulin to the mother. The standard dose (300 µg) is sufficient to prevent maternal immunization for fetal transfusions of up to 15 mL of red blood cells or 30 mL of whole blood.

MEDICAL AND SURGICAL PROBLEMS IN THE PREGNANT PATIENT

Perspective

Clinicians must be aware of a variety of illnesses, both related and unrelated to pregnancy, that may have altered symptomatology, risk, and treatment in the pregnant patient (Tables 176-2 and 176-3).

Abdominal Pain

Gynecologic Problems

Several gynecologic diseases must be considered in evaluating the pregnant patient who has abdominal pain. These include threatened miscarriage and ectopic pregnancy, which were discussed previously in this chapter. A patient with either complication of pregnancy can complain of nonspecific abdominal pain, either in the midline or laterally, and may show intermittent or constant symptoms. A careful history can be helpful in differentiating gradual progression of inflammatory or infectious diseases (e.g., ovarian cyst expansion or, rarely, PID) from sudden peritonitis caused by spillage of blood or cyst fluid into the peritoneal cavity or from the colicky pain of renal stones or the ischemic pain of ovarian torsion. In addition, examination of the abdomen, back, and pelvis helps localize the pain to areas and specific organs, thus narrowing
Appendicitis

**Perspective.** Appendicitis is the most common surgical emergency in pregnant patients. The incidence of appendicitis in pregnant patients is the same as that in nonpregnant patients, but delays in diagnosis contribute to an increased rate of perforation, which results in significant fetal mortality and maternal morbidity. During the first half of pregnancy, diagnostic findings are usually similar to those in the nonpregnant woman, but the clinical picture becomes less classic during the second half of pregnancy.

DIC, disseminated intravascular coagulation; hCG, human chorionic gonadotropin; HELLP, hemolysis, elevated liver enzymes, low platelets; PIH, pregnancy-induced hypertension.
Pyelonephritis, cholecystitis, and pregnancy-related diseases such as ectopic pregnancy, broad ligament pain, corpus luteum cyst leakage, and ovarian torsion must be considered in the patient who has right-sided abdominal pain. Pyelonephritis is the most common condition that is confused with appendicitis. During its migration, the appendix takes up a position very near the kidney, resulting in a high incidence of pyuria and flank pain (see Fig. 176-8). In cases of appendicitis, unless there is coincident urinary tract infection, the urine is free of bacteria, a feature distinguishing it from pyelonephritis. Salpingitis, another common misdiagnosis, is very rare in pregnancy, although it can occur before 12 weeks of gestation.

**Diagnostic Strategies.** Leukocytosis is common in pregnant patients with appendicitis, although it is rarely high enough to distinguish it from the physiologic leukocytosis of pregnancy. Pyuria in a catheterized urine specimen suggests pyelonephritis, but it is also seen in 20% of patients with appendicitis. Bacteruria is uncommon. Ultrasonography, using graded-compression techniques, may reveal a noncompressible tubular structure in the right lower quadrant consistent with appendicitis. Studies regarding the diagnostic utility of ultrasonography in the diagnosis of appendicitis are limited but suggest that it has a high positive predictive value but a low negative predictive value. Given the low radiation risk to the fetus, the noninvasive nature of the test, and its utility in evaluating other complications, some authors have recommended that ultrasonography should be the initial test of choice when appendicitis is suspected, especially in the first and second trimesters. Castro and colleagues reported the utility of helical CT in diagnosis, with fetal radiation exposures of only 300 mrad, using rectal contrast and a limited study. Otherwise, laparoscopy or laparotomy is the diagnostic procedure of choice in the pregnant patient suspected of having appendicitis. Early exploration is to be encouraged even more in pregnant than in nonpregnant patients because of the variability of clinical signs and the increased fetal risk if diagnosis is delayed.

**Management.** The pregnant patient with suspected appendicitis should be admitted to the hospital after appropriate consultation with surgeons and obstetricians. Ultrasonography or CT scan should be considered as diagnostic options. The patient should be kept on nothing by mouth (NPO) status, with intravenous fluid hydration to maintain intravascular volume. Although prompt surgery is required if the diagnosis is clear, in unclear cases a period of inpatient observation may allow clarification of signs and symptoms.

**Gallbladder Disease**

**Perspective.** Cholelithiasis is present in approximately 5% of pregnant women and is the second most common nonobstetric surgical condition in pregnant patients. The natural history of asymptomatic cholelithiasis is believed to be similar to that in nonpregnant women, with less than half of patients with gallstones developing symptoms.

**Principles of Disease.** Changes in gallbladder kinetics are believed to be due to high pregnancy-related steroid levels. Progesterone decreases smooth muscle tone and induces gallbladder hypomotility and cholestasis, causing an increased risk of stone formation. In addition, pregnancy induces changes in bile composition and increased cholesterol secretion, thus increasing the incidence of cholesterol stone formation.

**Clinical Features.** The signs and symptoms of acute cholecystitis during pregnancy are the same as those in nonpregnant
women, Epigastric or right upper quadrant pain and tenderness and nausea predominate. Leukocytosis must be interpreted carefully because of the increased white blood cell count seen normally in pregnancy. Likewise, a slightly elevated amylase level can be normal during pregnancy, and alkaline phosphatase, which is produced by the placenta, may be twice the nonpregnant level. A history of self-limited pain episodes associated with food intake is useful in suggesting the diagnosis.

Diagnostic Strategies. Ultrasonography is a reliable means of recognizing stones within the gallbladder, although it may not differentiate symptomatic from asymptomatic stones. In the patient with right upper quadrant pain, simultaneous sonographic evaluation of the liver is useful but technically difficult, particularly during the third trimester, when subcapsular liver hematomas and other intrinsic hepatocellular disease can occur but the liver may be obscured under the ribs.

Differential Considerations. Pyelonephritis should always be considered in the patient with right upper quadrant pain with or without fever. During the third trimester, appendicitis can also be associated with right upper quadrant pain. Hepatitis and fatty liver infiltration occur in pregnancy; liver distention and inflammation associated with pregnancy-induced hypertension can also cause right upper quadrant pain. In addition, spontaneous intrahepatic bleeding can occur in late pregnancy, mimicking cholecystitis. Because of the potential for other serious diseases, diagnostic studies should always be performed to verify a clinical diagnosis of symptomatic cholelithiasis and cholecystitis in pregnancy.

Management. The patient who has fever, leukocytosis, prolonged pain, or evidence of cholecystitis should be made NPO and given IV fluid hydration, adequate pain control, and broad-spectrum antibiotics. These patients must be admitted for inpatient management. Some patients can be managed medically for prolonged or complicated cholecystitis. Patients with obstructive jaundice, gallstone pancreatitis, or sepsis or patients who fail conservative management should have surgery. Discharge should be considered only in patients with uncomplicated and sonographically proven cholelithiasis who do not meet admission criteria after consultation with an obstetrician. Pregnant patients with symptomatic cholelithiasis have a high rate of symptomatic relapse and increased severity of disease with each relapse.

Liver Disorders

Perspective. Pregnancy is associated with several unique liver abnormalities in addition to more usual hepatic diseases. Clinicians should recognize the various symptoms of liver disease during pregnancy as well as the hepatic diseases unique to pregnant women. Liver metabolism increases during pregnancy, but hepatic blood flow is unchanged and little change occurs in liver function. Bilirubin, transaminases, lactate dehydrogenase, and prothrombin times are unchanged from the nonpregnant state. Albumin levels decrease secondary to an increase in maternal circulating plasma volume. Alkaline phosphatase levels may be up to double the nonpregnant values, and amylase levels may also be slightly elevated.

Hepatitis. Hepatitis is the most common cause of liver disease in pregnancy, accounting for 40% of cases of jaundice in pregnancy. Management and treatment are supportive and unchanged from those for nonpregnant patients. Hepatitis E, however, has been reported to have a more aggressive course in pregnancy. Maintaining adequate nutrition is a priority. Vertical transmission of hepatitis B can occur if the disease is not recognized. Prophylaxis should be administered to the newborn.

Acute Fatty Liver of Pregnancy. Acute fatty liver of pregnancy is a disorder of the third trimester that can result in hepatic failure, complicated labor, and fetal mortality. The disease is rare, occurring most often in primiparous patients and patients with twin gestations.

Principles of Disease. The cause of acute fatty liver of pregnancy is unknown, although studies suggest that a deficiency in the fetus’s fatty acid metabolism leads to an accumulation of hepatotoxic metabolites in the maternal circulation.

Microscopically, fatty infiltration of the hepatocytes with edema and vacuolization can be seen, but there is no necrosis or inflammation. Liver function returns to normal after delivery if the patient can be supported through the acute phase. Although up to 50% of patients have signs of preeclampsia, the two are not clearly related. The diagnosis must be differentiated from viral hepatitis and HELLP syndrome, which have similar disease presentations and laboratory findings but, again, are not clearly related.

Clinical Features. Nausea and vomiting or liver dysfunction during the third trimester should trigger consideration of a diagnosis of acute fatty liver. In addition, nonspecific flulike symptoms, such as anorexia, fatigue, and headache, occur initially. The right upper quadrant and/or epigastric is usually tender. The disease may progress to coagulopathy, jaundice, seizures, disseminated intravascular coagulation, and hepatic encephalopathy. The diagnosis is often delayed secondary to the multiple differential considerations.

Diagnostic Strategies. Typically, leukocytosis is present, the platelet count and fibrinogen level are low, prothrombin time and partial thromboplastin time are elevated, and fibrin split products are present. Hypoglycemia may occur. Serum transaminase levels are elevated, although rarely above 1000 U/L (a distinguishing feature from hepatitis), and should be measured in all patients who have systemic gastrointestinal symptoms during the third trimester. In contrast to Reye’s syndrome, the serum ammonia level is only mildly elevated. Hyperuricemia is usually present. Bilirubin is elevated late in the course of the disease. The CT scan is usually normal, as is the sonogram. Liver biopsy is used to make the definitive diagnosis.

Differential Considerations. Liver tenderness and coagulopathy most often suggest preeclampsia during the third trimester. Jaundice and increases in aminotransferase level are distinguishing features because they are unusual in cases of liver disease associated with pregnancy-induced hypertension. Similarly, rapid progression of hepatic failure, hypoglycemia, and coagulopathy is unlikely in cases of preeclampsia. The patient with viral hepatitis is likely to have more marked elevations in transaminase levels. Drug-induced hepatic failure should be excluded by history and toxicologic screen for acetaminophen or other toxins if appropriate. Cholecystitis may be distinguished by ultrasound, but it may also be characterized by right upper quadrant pain; it is not associated with coagulopathy or progressive liver failure.

Management. The patient with acute fatty liver of pregnancy requires immediate stabilization if experiencing seizure or coma. Hypoglycemia may occur, which should be rapidly corrected with dextrose. Coagulation parameters should be assessed. Fluid resuscitation and replacement of clotting factors may be required, and the patient should be admitted to an obstetric service capable of managing this serious disease. The diagnosis is usually made with liver biopsy if the disease
has not progressed to severe coagulopathy. Rapid delivery is usually advisable when the diagnosis has been established. The route of delivery is dictated by the patient’s clinical course and hemodynamic status. Fresh frozen plasma, platelet transfusions, and glucose may be needed to sustain the patient until delivery can be accomplished. After delivery, infants of mothers with acute fatty liver of pregnancy are at risk for postpartum hypoglycemia and liver dysfunction and therefore should be monitored closely.82

Intrahepatic Cholestasis of Pregnancy. Intrahepatic cholestasis of pregnancy, also termed idiopathic jaundice of pregnancy, icterus gravidarum, or pruritus gravidarum, is a rare syndrome that occurs during the third trimester of pregnancy. It is the second most common cause of jaundice in pregnancy, after hepatitis. Histologically, the disease is characterized by cholestasis and dilated canaliculi in the biliary tree. The liver is normal. It is more common with increasing maternal age, with multiple gestations, and in the winter months.76,80

Clinical Features. Generalized pruritus and mild jaundice are the hallmarks of intrahepatic cholestasis of pregnancy. Only 20% of patients present with this combination, however, and 80% present with pruritus alone. The pruritus usually begins in the palms and soles and ascends to the trunk. Although insomnia and fatigue occasionally accompany the pruritus, the patient appears nontoxic, without fever, vomiting, diarrhea, or significant malaise. The bilirubin level is rarely above 5 mg/dL, the alkaline phosphatase level can be elevated 7- to 10-fold, and transaminase levels are in the normal range. Resolution occurs when the woman delivers. Although maternal outcome is favorable, women with intrahepatic cholestasis of pregnancy are at increased risk for preterm delivery, meconium passage, and intrauterine fetal demise.76,80,83

Differential Considerations and Management. Exclusion of more serious entities, such as viral hepatitis, acute fatty liver, drug-induced cholestasis, or complicated cholecystitis, is required. Outpatient management is appropriate, provided the diagnosis is clear and the patient has close obstetric follow-up. Some authors advocate aggressive fetal surveillance and delivery after fetal lung maturity to improve fetal outcome.76 Symptomatic treatment with antihistamines, ursodeoxycholic acid, bile salts, guaiphenesin, and other medications has been tried with variable success.80,84

Hyperemesis Gravidarum

Nausea and vomiting are common in pregnancy, particularly from 6 to 20 weeks of gestation. Hyperemesis gravidarum is defined as nausea and vomiting that causes starvation metabolism, weight loss, dehydration, and prolonged ketonemia and ketonuria. It occurs in a small minority of pregnant patients. The cause of hyperemesis gravidarum is not clear; associations have been made with increasing estradiol and hCG levels, as well as with maternal cytokines.85,86 Several studies have suggested an increased infection rate with Helicobacter pylori in patients with hyperemesis gravidarum.87-89 Initial management involves rehydration with intravenous fluids, antiemetics, and demonstration of ability to take oral hydration. Patients may require enteral nutrition. Most standard antiemetics are in Food and Drug Administration category C and are used successfully to treat hyperemesis gravidarum. A short course of oral prednisolone has been reported to be therapeutic for intractable hyperemesis.80,81 Oral vitamin B6 has also been reported to be helpful.89 Bilirubin and alkaline phosphatase levels can be mildly elevated but should return to normal levels after delivery. Hyperemesis may be complicated by liver disease and abnormal liver function tests, which are expected to resolve with supportive treatment.82

Thromboembolic Disease in Pregnancy

Principles of Disease

Thromboembolic disease accounts for almost 20% of obstetric mortality, making it the leading cause of death in pregnancy.16 Pregnancy is a hypercoagulable state, with increased coagulation factors and stasis as pregnancy progresses and significant vascular trauma at the time of delivery. The risk of venous thrombosis increases during pregnancy to five or six times that of nonpregnant women. Although the risk is increased throughout pregnancy, it is highest during the puerperium. Women who smoke, are overweight, are older than 35 years, have varicose veins, or have a prior superficial venous thrombosis or history of a hypercoagulable state, as well as women who deliver prematurely or have postpartum hemorrhage, are at higher risk.93-96

Clinical Features

As in nonpregnant patients, clinical signs of pain, tenderness, and swelling are poor predictors of deep vein thrombosis in pregnancy. The clinical diagnosis of pulmonary embolus is likewise difficult. Although tachypnea, tachycardia, dyspnea, and pleuritic pain are commonly associated with pulmonary embolus, the symptoms are nonspecific and may be associated with such diverse diseases as hepatic inflammation, pyleonephritis, and diaphragmatic impingement from a normal gravid uterus.

Diagnostic Strategies

An arterial blood gas analysis should be undertaken, although it may be difficult to interpret. Arterial blood gases in pregnancy normally show a respiratory alkalosis from progesterone-induced respiratory stimulation, and the alveolar-arterial (A-a) oxygen difference is normal (the pregnant normal A-a gradient can be as high as 20 mm Hg) in the majority of patients with pulmonary embolus.97 A chest radiograph (shielding the pelvis and uterus) should be obtained to exclude other disease processes that may mimic a pulmonary embolus. The diaphragm is normally symmetrically elevated during late pregnancy.

Noninvasive impedance plethysmography is highly accurate for the exclusion of deep vein thrombosis but lacks sensitivity for the exclusion of nonobstructive thrombi. Due to its widespread availability, Doppler ultrasonography has superseded noninvasive impedance plethysmography as the first-line test for the diagnosis of deep venous thrombosis. Both tests, however, are useful in the diagnosis of deep vein thrombosis of the femoral or popliteal veins in pregnancy, and these studies provide the least risk to the patient. Abnormal flow study results can be found in the normal patient studied in the supine position during late pregnancy, so positive results should be confirmed with the patient positioned on her left side. An unequivocally abnormal flow study finding is sufficient reason to treat the pregnant patient in most cases. However, normal leg study results can be seen with isolated iliac vein disease, which is common in pregnancy and requires imaging with magnetic resonance imaging or CT for diagnosis. If thromboembolic disease is suspected, serial indirect Doppler testing or CT may be required.98 The risk of anticoagulation usually outweighs the risk of definitive studies when the diagnosis is equivocal.

Technetium-labeled ventilation-perfusion scans expose the fetus to less than 50 mrad of radiation, making them safe in all trimesters. One study found that only 2% of pregnant women
had high-probability scans; no adverse events occurred during follow-up in 104 women who were not heparinized and had normal or nondiagnostic scans. Helical CT scanning provides an alternative for the diagnosis of pulmonary embolus in pregnancy. The average fetal radiation dose in helical CT scans is less than that from ventilation-perfusion scans, making it a potentially attractive alternative, although studies of its accuracy in pregnancy have not been done. A pulmonary angiogram may be required if the diagnosis of pulmonary embolus is unclear after less invasive studies have been performed.

Management

Warfarin (Coumadin) is contraindicated during pregnancy because of its teratogenic effects and high risk of abortions and fetal hemorrhage. Heparinoids are used to treat thromboembolic disease during pregnancy. Unfractionated heparin carries a poorly understood risk of fetal osteoporosis, thrombocytopenia, prematurity, or miscarriage. In general, acute anticoagulation with intravenous heparin is followed by subcutaneous heparin twice daily, usually continued for 3 to 6 months postpartum in patients who have deep vein thrombosis or pulmonary embolus during pregnancy. Patients receiving this treatment require laboratory testing every 1 to 2 weeks, and the efficacy of anticoagulation may be variable in pregnancy. Low-molecular-weight heparin is considered safe in pregnancy and offers several advantages over unfractionated heparin: decreased bleeding risk, reliable pharmacokinetics, decreased risk of heparin-induced thrombocytopenia, fixed dosages, less frequent dosing, and decreased risk of osteoporosis and thrombocytopenia. In patients with a history of deep vein thrombosis or pulmonary embolus, prophylaxis for subsequent gestations is usually recommended.

Genitourinary Infections

Urinary Tract Infection

**Principles of Disease.** Although the risk of asymptomatic bacteruria (9%) does not increase in pregnancy, it appears that pregnancy predisposes the patient to develop symptomatic lower and upper tract genitourinary infections. Uterine pressure exerted on the bladder and ureters, poor emptying of the bladder with voiding, and progesterone-induced smooth muscle relaxation that inhibits ureteral peristalsis all appear to contribute to increased risk of infection during pregnancy.

Identification of patients with asymptomatic bacteruria by prenatal screening in early pregnancy identifies approximately 95% of individuals at risk for subsequent bacteruria during the pregnancy. Because up to 30% of women who have asymptomatic bacteruria will develop pyelonephritis if untreated, treatment of bacteruria is cost-effective and important.

**Clinical Features and Diagnostic Strategies.** The pregnant patient who comes to the emergency department with lower urinary tract symptoms (e.g., dysuria, frequency, and urgency) or upper tract symptoms (e.g., fever, malaise, or back pain) should have a pelvic examination and evaluation of an uncontaminated urine specimen (preferably catheterized). There is a predominance of right-sided symptoms during pregnancy, probably the result of increased mechanical forces on the right ureter, but left-sided flank pain or bilateral symptoms may be caused by pyelonephritis. Rarely, urinalysis may yield normal results or cultures may produce negative findings, either because of failure to report lower colony counts or because of complete obstruction of the involved ureter.

The major risk of asymptomatic and lower urinary tract infection is spread to the renal parenchyma. Acute pyelonephritis carries considerable morbidity in pregnancy, including maternal sepsis, permanent renal injury, and premature labor. The risk of prematurity can be minimized by effective treatment and continued monitoring for recurrence. The development of premature labor in the woman who has pyelonephritis is ominous and can be prevented only by aggressive recognition and treatment earlier in pregnancy.

**Differential Considerations.** Vaginitis, herpes genitalis, chlamydial infection of the urethra, or ovarian torsion can masquerade as urinary tract symptoms. A history of external dysuria (burning at the perineum with urination) suggests herpes or vaginitis. A pelvic examination should be performed to obtain cervical cultures and to identify perineal or vaginal causes of dysuria. Appendicitis, cholecystitis, pancreatitis, and liver diseases in pregnancy must be considered in the differential diagnosis of upper urinary tract infection. Back pain may also be a sign of premature labor. Careful evaluation of an uncontaminated catheterized urine specimen is essential to making the correct diagnosis.

**Management.** Patients with asymptomatic bacteruria or lower urinary tract signs and symptoms should be treated with 7 to 10 days of an antibiotic that is active against usual urinary pathogens and is safe in pregnancy. The most common choices are a cephalosporin, a nitrofuran, or a sulfonamide (except during the third trimester). Single-dose therapy for these infections during pregnancy has been proposed but may not be appropriate in an emergency department population with questionable follow-up and a relatively high incidence of occult upper urinary tract infection.

Patients with fever, back pain, and evidence of acute pyelonephritis in pregnancy are usually admitted for intravenous antibiotic administration, although outpatient parenteral therapy can be effective and safe in selected patients. In such cases, aggressive intravenous hydration, obstetric consultation, and urine cultures should be initiated. At least one parenteral dose of antibiotics should be given, with antibiotic coverage guided by known organism susceptibilities in a given hospital. Because the resistance of *Escherichia coli* to ampicillin is considerable in most regions, cephalosporin or a combination of a penicillin and an aminoglycoside (which must be carefully monitored because of variable clearance by infected kidneys) is the usual intravenous medication administered. Cultures must be performed to ensure that the original choice of antibiotic was correct, and the patient must have a repeat culture and be followed closely after treatment.

Vaginitis

**Bacterial Vaginosis.** Bacterial vaginosis (formally known as *Gardnerella* vaginosis or *Haemophilus vaginalis* vaginitis) is an overgrowth of multiple endogenous vaginal bacteria, in some cases producing excessive discharge and vaginal malodor. Prevalence rates for bacterial vaginosis in pregnancy are estimated at 15 to 20%. Bacterial vaginosis is associated with an increased risk of chorioamnionitis, subclinical PID, premature rupture of membranes, fetal prematurity, and postpartum endometritis after vaginal delivery. Therapy during the second trimester is recommended even when the patient is asymptomatic to prevent the sequelae of premature rupture of membranes. Management includes a 7-day course of metronidazole or a 7-day course of clindamycin. Intravaginal treatment is not recommended in pregnant patients.

**Candida albicans Vaginitis.** The incidence of vulvovaginal candidiasis is increased during pregnancy by high levels of estrogen and other steroids. It is not increased in the pregnant patient
Chlamydia trachomatis and Herpes simplex virus infections pose a risk to the pregnant patient. Gonococcal infection of the cervix is similar to that in nonpregnant women. Salpingitis is rare but may develop during the first trimester from upper genital tract infection. Some practitioners believe that the incidence of the disseminated infection is increased in pregnant patients because of elevated progesterone levels and increased vascularity in the area of the cervix. Gonococcal arthritis is the most common manifestation of gonococcal dissemination. Diagnosis and treatment of gonococcal infections are unchanged by pregnancy, and treatment includes cephalosporins or spectinomycin. Treatment for possible coexistent chlamydial infection is recommended for pregnant and nonpregnant women. The major complications of third-trimester gonococcal infection are neonatal gonococcal ophthalmia and sepsis.

### Sexually Transmitted Diseases in Pregnancy

Sexually transmitted diseases are treated in pregnant patients according to the latest Centers for Disease Control and Prevention guidelines. In general, the tetracyclines and quinolones are contraindicated in pregnant patients. Treatment of genitalic tract infections may be important in preventing preterm labor and the morbidity of prematurity.

**Chlamydia trachomatis Infection.** *Chlamydia trachomatis* infection is the most common sexually transmitted disease, both in the United States and worldwide. Its prevalence is currently three to five times that of *Neisseria gonorrhoeae* infection. Clinical diagnosis is difficult during pregnancy because cervical mucus is usually cloudy and contains white blood cells. Routine chlamydia screening during pregnancy is important to prevent complications of preterm labor and postpartum endometritis, both of which are more common in patients who have chlamydial cervical infections. Chlamydial infections of infants born to infected mothers include conjunctivitis and pneumonia. Treatment during pregnancy or breast-feeding is azithromycin (single 1-g dose), which improves compliance and decreases gastrointestinal side effects. Treatment with a 7-day course of erythromycin base or amoxicillin is an acceptable alternative. Tetracyclines are contraindicated in pregnancy.

**Herpes Simplex Infection.** Herpes simplex virus infections pose a significant risk to pregnancy both to the mother and the newborn. Women who have genital herpes during the third trimester have a 30 to 50% increased risk of transmission compared with women with herpes simplex virus infection in the first trimester (1%). The virus can be transmitted prenatally via transplacental infection or ascending vaginal infection and via vaginal delivery, particularly when herpetic lesions are present. Infections in the neonate often are disseminated or involve the central nervous system, causing significant morbidity and mortality. In the emergency department, culturing of new suspected herpetic lesions of the cervix, vagina, or perineum identifies patients at risk for perinatal complications. Although the risk of oral acyclovir and valacyclovir use in pregnancy is not well-known, it is recommended for first-episode genital herpes.Suppressive therapy can reduce the need for cesarean section in women whose first clinical episode of genital herpes simplex virus occurred during pregnancy but may not eliminate the need for cesarean section in women with recurrent herpes simplex virus. Treatment should be undertaken with obstetric consultation and careful patient monitoring.

**Neisseria gonorrhoeae Infection.** Gonococcal infection of the cervix occurs during pregnancy in 1% of women. Symptoms are similar to those in nonpregnant women. Salpingitis is rare but may develop during the first trimester from upper genital extension of cervical infection. Some practitioners believe that the incidence of the disseminated infection is increased in pregnant patients because of elevated progesterone levels and increased vascularity in the area of the cervix. Gonococcal arthritis is the most common manifestation of gonococcal dissemination. Diagnosis and treatment of gonococcal infections are unchanged by pregnancy, and treatment includes cephalosporins or spectinomycin. Treatment for possible coexistent chlamydial infection is recommended for pregnant and nonpregnant women. The major complications of third-trimester gonococcal infection are neonatal gonococcal ophthalmia and sepsis.

### Upper Genital Tract Infection

**Pelvic Inflammatory Disease.** Pelvic inflammatory disease is very rare in pregnancy and does not occur after the first trimester. Differential diagnosis includes ectopic pregnancy, septic abortion, and appendicitis, all of which are more common. In the patient with suspected infection, smears or cultures for chlamydia and gonorrhea should be obtained. Given the risk of endometrial infection in pregnancy and the need to consider other diagnoses, pregnant patients who have suspected PID require hospital admission and intravenous antibiotics.

**Chorioamnionitis.** Chorioamnionitis is the infection or inflammation of the placenta and fetal membranes. After 16 weeks of pregnancy, the chorioamniotic membranes adhere to the cervical os and may become infected. The risk is increased in women with preterm labor. Chorioamnionitis is diagnosed by the findings of fever, maternal and fetal tachycardia, and uterine tenderness in a patient past 16 weeks of pregnancy. Leukocytosis can be suggestive of chorioamnionitis but is not diagnostic. The diagnosis is confirmed by amniocentesis. Patients should have blood cultures drawn. Vaginal and cervical cultures for group B strep, *E. coli*, chlamydia, and gonorrhea should also be obtained. Urgent obstetric consultation should be obtained, and hospital admission for intravenous antibiotics is required. Patients are usually treated with intravenous ampicillin and gentamicin. Vancomycin, clindamycin, or erythromycin may be substituted in the penicillin allergic patient.

**Acknowledgment**

We thank Dr. Jean Abbott for her work on prior editions of this chapter.
The emergency physician must determine the type of miscarriage (incomplete, complete, inevitable, and threatened) because management priorities for these patients are different.

The history and the physical examination of the patient with ectopic pregnancy are insensitive and nonspecific; therefore, ancillary studies are required to locate the pregnancy in any emergency department patient who has abdominal pain or vaginal bleeding and a positive pregnancy test result.

The major conditions associated with vaginal bleeding in the second half of pregnancy include abruptio placentae and placenta previa. Patient history, physical examination, and results of ultrasonography must be used together by the emergency physician to distinguish these conditions.

Appendicitis is the most common surgical emergency in pregnancy, and the presentation of these patients may not be classic, leading to a misdiagnosis rate of 30 to 35% overall in pregnant patients.

The treatment of eclampsia includes magnesium sulfate for seizures, reduction of blood pressure, and delivery of the fetus.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
This chapter focuses on the care of the pregnant patient with selected chronic medical illnesses. Recognition of chronic disease is an important aspect of screening in these patients and can prevent adverse outcomes for both the mother and the fetus.

### PRINCIPLES OF DISEASE

The physiologic changes that occur in pregnancy may exceed the patient’s underlying compensatory mechanisms, resulting in initial symptom onset or rapid decompensation of medical illness during pregnancy. Certain chronic medical conditions also pose a serious threat to the mother’s health or result in a poor fetal outcome. Finally, some medical illnesses result in a difficult delivery or the need for special resuscitation measures in the neonate.

The incidence of pregnancy in chronically ill patients is increasing because of improved survival of patients with diseases such as diabetes, epilepsy, renal failure, and various cancers. Also, the demographics of pregnancy are changing in that maternal age at the time of first pregnancy is increasing. Advances in assisted reproduction, including in vitro fertilization and oocyte donation, have made it possible for older women—including those who are postmenopausal—to become pregnant. Older pregnant women experience an increased rate of antepartum and intrapartum complications and are more likely to have comorbid conditions such as cardiovascular disease.

### SPECIFIC DISORDERS

#### Asthma

Asthma is the most common pulmonary problem in pregnancy, affecting up to 8.4% of gestations, and the prevalence appears to be increasing. The overall effect of pregnancy on asthma seems to be that one third of patients will experience improvement, and the other third remain unchanged. The exact effect of asthma on the fetus remains controversial. Some studies show an increased risk of complications including preeclampsia, gestational diabetes mellitus, prematurity, and intrauterine growth retardation.

Several changes in respiratory physiology during normal pregnancy affect the management of asthma in this context; both the tidal volume and the minute ventilation rise, increasing up to 50% by term. This increase in minute ventilation, or “hyperventilation of pregnancy,” lowers the resting $PCO_2$ by an average of 8 to 10 mm Hg to a $PCO_2$ of 32 mm Hg. In response to chronic hyperventilation, there is a compensatory increase in the renal excretion of bicarbonate, with serum levels averaging 19 mEq/mL. The net result is a slight respiratory alkalosis, with a serum pH ranging from 7.40 to 7.45. It is important to keep these “normal” values in mind when gauging the severity of an asthma exacerbation in the pregnant patient.

The treatment strategy in the care of the pregnant asthmatic patient is to achieve normal pulmonary function, prevent acute exacerbations, and minimize use of short-acting rescue beta-agonists. Acute asthma exacerbations pose a significant maternal and fetal risk, and the pregnant patient should be managed as aggressively as the nonpregnant patient. In fact, patients whose asthma is well controlled are generally expected to have normal pregnancies, and the risks from inadequately treated disease outweigh the risks of therapy.

The inhaled beta-agonist agents are generally considered as safe in pregnancy (Tables 177-1 and 177-2). As in the nonpregnant patient, inhaled short-acting beta-agonists are first-line agents for acute asthma exacerbations. Long-acting agonists are also recommended for maintenance use in patients with moderate or severe disease. Although safe from a teratogenic perspective, these medications are powerful tocolytics and will usually halt active labor. Selective agonists are preferred because nonselective agents such as epinephrine theoretically decrease uteroplacental blood flow via beta-mediated effects.

Corticosteroids remain a core component of maintenance treatment for asthma in the pregnant patient. In fact, current data support the safety of inhaled corticosteroids, and their chronic use is recommended in all asthmatic patients except those with mild intermittent disease. Use of systemic corticosteroids is sometimes necessary on a chronic basis in patients with severe persistent asthma and as a short burst in patients with exacerbations that exhibit inadequate or poor response to initial beta-agonist therapy. However, corticosteroids have a possible association with cleft deformities, preterm delivery, low birth weight, and preeclampsia. These complications may also be related to uncontrolled asthma, but inhaled delivery is preferred over systemic dosing.

The methylxanthine theophylline has been shown to be safe in pregnancy at therapeutic doses and is an acceptable alternative medication for maintenance therapy. There are limited data for chromolyn sodium and the newer leukotriene receptor antagonists (montelukast and zafirlukast), but all are

<tr>
<td>Hyperthyroidism</td>
<td>Fetal—PTD, low birth weight, fetal thyroid dysfunction, fetal loss</td>
<td>Management of thyroid storm is the same as for the nonpregnant patient and includes a search for the underlying precipitant. Therapy for hyperthyroidism in the absence of thyroid storm: <strong>Reversal of sympathetic effects:</strong> propanolol in standard doses is useful until thyroid hormone synthesis has been blocked by thioamides. <strong>Thioamides:</strong> both propylthiouracil and methimazole at the lowest effective dose are acceptable. <strong>Surgical therapy:</strong> thyroidectomy is useful in refractory cases. <strong>Other:</strong> avoid iodide if possible; hydrocortisone decreases peripheral conversion of ( \Gamma_1 ) to the more active ( \Gamma_3 ) and can be used during pregnancy. Radioactive iodine is absolutely contraindicated.</td>
</tr>
<tr>
<td>Hypothyroidism</td>
<td>Fetal—congenital malformations, low birth weight, fetal loss, fetal thyroid dysfunction, and goiter</td>
<td>Maintenance therapy includes levothyroxine 0.15 mg/day. Appropriate treatment prevents adverse obstetric and fetal outcomes. Myxedema coma is rare, but when present, treatment is the same as for the nonpregnant patient.</td>
</tr>
<tr>
<td>Tuberculosis</td>
<td>Fetal—fetal loss, low birth weight, PTD; fetal and neonatal tuberculosis</td>
<td><strong>PPD positive/ chest radiograph negative:</strong> 6–9-month course of isoniazid (starting after the first trimester) for patients with recent conversion (&lt;2 years); patients who have been PPD positive ≥2 years may defer treatment until after delivery but should still be offered a course of isoniazid since it is safe in pregnancy. <strong>Active tuberculosis:</strong> 9-month course (starting immediately) of isoniazid plus rifampin or ethambutol. <strong>Multidrug-resistant tuberculosis:</strong> warrants aggressive therapy without regard to potential teratogenicity. Pyridoxine is mandatory for all patients receiving isoniazid. <strong>Antiretroviral therapy:</strong> 1. Highly active antiretroviral therapy (HAART) should be offered to all pregnant patients with HIV and viral load &gt;1000. The HAART regimen should include zidovudine (AZT) to prevent vertical transmission of the virus. 2. There are specific HAART drug-related concerns during pregnancy—decisions regarding therapy are best made by appropriate specialists. 3. AZT monotherapy is not recommended except in those patients with a low viral load who do not wish to take HAART. In these cases, AZT is appropriate to reduce disease transmission. Cesarean section is recommended with viral load &gt;1000. Opportunistic infections require standard therapies despite the potential fetal effects.</td>
</tr>
<tr>
<td>HIV/AIDS</td>
<td>Fetal—HIV infection, PTD, fetal loss; neonatal drug withdrawal if the mother uses intravenous drugs</td>
<td></td>
</tr>
<tr>
<td>Syphilis</td>
<td>Fetal—congenital syphilis, fetal loss, PTD, IUGR, nonimmune hydrops</td>
<td>Primary, secondary, early latent (&lt;1 year): benzathine penicillin G (BPG), 2.4 million units IM × one dose Late latent (&gt;1 year or unknown duration): BPG, 2.4 million units IM weekly × three doses Neurosyphilis: aqueous penicillin G, 2–4 million units IV q4h × 10–14 days or procaine penicillin G, 2.4 million units IM, and probenecid, 500 mg PO q6h × 10–14 days</td>

*Defined as blood pressure ≥140 mm Hg systolic or ≥90 mm Hg diastolic.

Methylsulfate has received a good deal of attention in the acute treatment of refractory asthma exacerbations because it has a wide safety profile and potent bronchodilator properties. Although large doses of magnesium have been used for the treatment of eclampsia, at this time there are insufficient data to support routine use of magnesium in this patient population.

Perhaps the most important tenet of treatment to recognize is that if the mother is hypoxic, the fetus is hypoxic as well. In addition, the fetus is more sensitive to hypoxia; thus, a normal maternal oxygen saturation does not preclude fetal distress. Supplemental oxygen should be administered to all pregnant patients with an acute asthma exacerbation.

**Hypertension**

**Chronic Hypertension and Hypertensive Emergencies**

Chronic hypertension is defined as elevated blood pressure that is present before the onset of pregnancy or that begins prior to the 20th week of gestation. It affects up to 5% of pregnancies and represents a significant source of maternal and fetal mortality and morbidity (see Table 177-1). The emergency physician may be required to provide therapy for hypertensive emergencies in patients with chronic hypertension and to differentiate between the various hypertensive disorders of pregnancy (Table 177-3).

In the treatment of chronic hypertension in pregnancy, the physician must balance the goal of reducing maternal blood
pressure with the requirements to maintain cardiac output and minimize adverse effects for both mother and fetus. Precipitous and marked decreases in blood pressure may significantly diminish uteroplacental blood flow. Treatment of patients with mild disease does not have an appreciable effect on perinatal outcomes, nor does it reduce the incidence of superimposed preeclampsia. In addition, these patients are likely to have a decrease in blood pressure without pharmacologic agents due to normal physiologic changes that occur in pregnancy, and they may be successfully managed without medications. On the contrary, patients with more severe hypertension, patients with evidence of end-organ damage, and patients on more than one pregestational antihypertensive medication probably need maintenance medical therapy (see Table 177-1). Lifestyle modification is a potential mode of therapy, but it is unclear whether dietary and weight restrictions are safe in the gravid patient.

Decisions regarding maintenance therapy are most appropriately made by the patient’s primary care practitioner in conjunction with her obstetrician. However, the emergency physician may be called upon to make treatment decisions for patients with severely elevated blood pressure and for patients with superimposed eclampsia. Nearly all of the major classes of antihypertensive agents are acceptable in the pregnant patient, with the exception of angiotensin enzyme inhibitors and angiotensin II receptor blockers. Diuretics are also considered second-line agents because of concerns regarding plasma volume constriction (see Table 177-1). Hydralazine and labetalol are the agents most commonly used for hypertensive emergencies associated with eclampsia and are also appropriate for such emergencies in the patient with chronic hypertension. Sodium nitroprusside can cause fetal cyanide toxicity after several hours of infusion and is considered a second-line agent (Table 177-4).

Diagnosis of preeclampsia in the pregnant patient with chronic hypertension is challenging but necessary (see Chapter 176). Patients with chronic hypertension are more likely to develop preeclampsia, a situation that results in increased morbidity and mortality compared with either process in isolation. Coexistence of the two disorders should be suspected in the following situations: (1) new onset of proteinuria after 20 weeks of gestation in a patient with known hypertension and (2) pregnant patients with hypertension and proteinuria prior to 20 weeks of gestation who develop thrombocytopenia, increased transaminase levels, or an acute increase in proteinuria or blood pressure (see Table 177-3).

### Pulmonary Hypertension

Primary (idiopathic) pulmonary hypertension, Eisenmenger’s syndrome (pulmonary hypertension associated with intracardiac left-to-right shunts), and secondary vascular pulmonary hypertension have extremely high mortality rates in association with pregnancy, ranging from 30 to 52%. The majority of deaths are a result of heart failure. Unfortunately, mortality is unaffected by peripartum management in most cases, although some patients benefit from selective pulmonary artery vasodilators such as prostacyclin and inhaled nitric oxide. The primary goals of the emergency physician are to ensure high right ventricular filling pressures by maintaining adequate volume status and to obtain early consultation with obstetrics and cardiology. Patients with early gestations should be referred for elective pregnancy termination.

### Cardiac Disorders

#### Acute Coronary Syndromes

Coronary artery disease is rare in pregnant women, with a population-based study noting a diagnosis of acute myocardial infarction (AMI) in up to 6.2 per 100,000 deliveries. Prior mortality rates were reported to be approximately 20%, but more recent studies reveal rates ranging from 5.1 to 7.3%. Normal physiologic changes of pregnancy such as increased cardiac output and reduced oxygen-carrying capacity secondary to physiologic anemia have the potential to exceed the threshold for angina if a fixed coronary artery stenosis is present. Certain conditions are also associated with an increased risk of pregnancy-related AMI, including advanced maternal age, thrombophilia, hypertensive disorders, anemia, diabetes mellitus, and tobacco use. AMI can occur anytime during the gestational period but peaks during the last trimester and peripartum period. Twenty-seven to 41% of events occur in the 6 weeks after delivery. Because increases in cardiac output peak during labor and delivery, maternal mortality from AMI is higher intrapartum than during the antepartum or postpartum periods.

A significant percentage of pregnant women with AMI have normal coronary arteries—reported to be 29% of those patients who underwent angiography. Other pathophysiologic mechanisms besides atherosclerosis that cause AMI in the pregnant patient include coronary artery dissection, coronary artery aneurysm, and vasospasm. The relative significance of these lesions varies according to the gestational period. Atherosclerotic disease causes the majority of AMIs in the antepartum period, whereas the incidence of coronary artery dissection is increased postpartum. Pulmonary embolus, reflux esophagitis, biliary colic, and aortic dissection are all more common than myocardial ischemia during pregnancy and need to be considered in the differential diagnosis. Unfortunately, some women continue to use illicit drugs during their pregnancy, and it is important to consider cocaine use in the pregnant patient presenting with chest pain.

#### Table 177-4 Antihypertensive Agents for Hypertensive Emergencies

<table>
<thead>
<tr>
<th>ANTIHYPERTENSIVE AGENT</th>
<th>DOSE</th>
<th>COMMENT</th>
</tr>

</table>

The diagnosis of angina is often clinical. Because normal pregnancy is often associated with electrocardiographic changes such as ST wave depression and T wave inversion, additional evaluation may be necessary. Echocardiography is useful in correlating suspicious electrocardiographic findings with wall motion abnormalities. The enzymatic diagnosis of myocardial infarction is unchanged except during and immediately after delivery, when troponin is preferred over creatinine kinase and myoglobin, which are both elevated above baseline during this time period. Angiography for the patient with suspected angina is generally avoided because the large dose of radiation poses a risk to the fetus, but it can be used in certain clinical situations with the preferred time of intervention being the second trimester. \(^{16}\) Radionuclide studies carry a lower radiation risk than does angiography but are also avoided unless absolutely necessary.

Treatment of AMI during pregnancy is similar in most respects to treatment of the nonpregnant patient. Survival of the mother is the primary concern, and therapy to improve maternal outcome should not be withheld. Standard treatment includes antiplatelet agents, nitroglycerin, beta-blockers, and antithrombotic agents. However, there are potential adverse effects of such therapy on the mother and fetus (see Table 177-1), and emergent consultation with cardiology is recommended. Regarding antiplatelet agents, aspirin remains the first-line agent. There is limited experience with clopidogrel and eptifibatide, but both have been used successfully and are considered safe from a teratogenic standpoint. Heparin has long been considered the antithrombotic agent of choice in pregnant patients, but newer low-molecular-weight agents, specifically dalteparin and enoxaparin, appear to be efficacious and safe and are deemed appropriate for use. \(^{21}\) Heparin is preferable for patients in the late third trimester because there is a more predictable response to protamine sulfate should labor begin.

Experience with thrombolytic therapy in pregnancy is extremely limited and is much more extensive in the setting of stroke and pulmonary embolism. \(^{22}\) Although such therapy may reduce maternal and fetal mortality, pregnancy is considered a relative contraindication to its use. Reported adverse effects have included maternal hemorrhage, maternal death, placental abruption, preterm delivery, fetal death, and fetal intracranial hemorrhage, although the causal relationship in many of these cases is unclear because neither tissue plasminogen activator nor streptokinase cross the placenta. The majority of patients who had favorable maternal and fetal outcomes, but most were being treated for indications other than AMI. \(^{20,22}\) Because thrombolytic therapy precludes major surgery and epidural anesthesia in the hours to days immediately after administration, the emergency physician must carefully consider whether to use these agents in pregnant women who are close to term, especially if the need for cesarean delivery is anticipated. Because of the lack of data and potential risks of fibrinolytics in gravida, emergent percutaneous intervention is the treatment of choice for definitive management of AMI.

In the setting of peripartum AMI, labor should be conducted with continuous monitoring of both the mother’s hemodynamic status and fetal well-being. There are benefits and risks of both vaginal and operative delivery. Cesarean section avoids prolonged exertion by the mother but subjects the patient to general anesthesia if use of antithrombotic agents precludes epidural catheter placement. In addition, surgical delivery places the patient at risk for typical postoperative complications, such as infection, hemorrhage, and thromboembolism. Therefore, assisted vaginal delivery is preferred unless there is an obstetric reason for cesarean section. \(^{20}\) Resolution of angina may occur during the postpartum period as physiologic demands lessen, but its occurrence during pregnancy merits a complete cardiac evaluation for acute coronary syndrome.

**Valvular Heart Disease**

Maternal valvular heart disease can be congenital or acquired and is one of the leading causes of nonobstetric death. Acquired valvular disease is mainly the result of rheumatic fever and endocarditis. In the United States, most cases of significant congenital heart disease are identified and corrected surgically before puberty. The ability of patients to tolerate pregnancy without significant adverse effects depends on the type and severity of the lesion. Mild to moderate lesions (New York Heart Association classes I and II) are often associated with good outcomes. On the other hand, mitral stenosis (beyond class I), advanced aortic stenosis, aortic and mitral lesions associated with moderate to severe ventricular dysfunction or pulmonary hypertension, and mechanical prosthetic valves requiring anticoagulation can result in significant maternal mortality and require directed therapy (see Table 177-1). \(^{16,23}\)

**Mitral Stenosis.** Mitral stenosis is the most commonly encountered valvular lesion in pregnancy and is also the most important lesion to detect in early pregnancy because maternal mortality is appreciable. \(^{16}\) The increased resting heart rate seen in normal pregnancy shortens left ventricular diastolic filling time and consequently results in decreased stroke volume. The demand for increased cardiac output during pregnancy creates a vicious cycle in which further acceleration of heart rate occurs. This tachycardia, combined with the expanded plasma volume of pregnancy, ultimately produces high left atrial pressures, pulmonary vascular congestion, and the symptoms and physical findings typical of left ventricular failure. Even patients with asymptomatic pregestational mitral stenosis warrant close cardiology follow-up with echocardiography at frequent intervals during gestation. \(^{16}\)

Treatment is aimed at reducing plasma volume and slowing the heart rate (see Table 177-1). Surgical intervention is indicated in patients with refractory symptoms despite optimal medical management and in patients with pulmonary hypertension. The preferred procedure is percutaneous balloon valvotomy, which is associated with good maternal and fetal outcomes when performed in experienced centers. \(^{16,23}\)

**Aortic and Mitral Regurgitation.** In most cases, chronic regurgitant lesions are well tolerated during pregnancy and may even improve as the reduced systemic vascular resistance of pregnancy allows more forward and less regurgitant flow. In addition, this effect is aided by the increase in heart rate and shortened diastole that occur in pregnancy. \(^{16,23}\) When necessary, medical therapy consists of diuretics and, possibly, vasodilators. Patients with acute mitral regurgitation due to ruptured chordae do not fare as well and may require surgical therapy. \(^{16,23}\)

**Aortic Stenosis.** Symptomatic aortic stenosis during pregnancy usually occurs in the setting of a congenital bicuspid valve and is uncommon. \(^{16,23}\) Patients with aortic stenosis tend to have good pregnancy outcomes, and conservative management is often possible. Severely symptomatic patients may need percutaneous valvotomy in an experienced institution, although this procedure is risky for both the mother and the fetus. \(^{16,23}\)

**Prosthetic Heart Valves.** Anticoagulation for the pregnant patient with a prosthetic heart valve is complicated. Warfarin is considered to be contraindicated during weeks 6 through 12 of gestation, although the risk of embryopathy is likely low when the dose is ≤5 mg/day. \(^{16,23}\) In addition, because warfarin crosses the placenta, there is a risk of fetal bleeding. Neither unfractionated heparin (UFH) nor low-molecular-weight heparin
Hematologic Disorders

Anemia

By far the most common medical complication of pregnancy is anemia. The physiologic adaptations to pregnancy include expansion of plasma volume in excess of the increase in red blood cell (RBC) mass. This results in the dilutional, physiologic anemia of pregnancy with nadir hemoglobin occurring near the beginning of the third trimester. Any type of anemia can complicate pregnancy, but the three types most commonly involved are iron deficiency, folate deficiency, and sickle cell hemoglobinopathy.

Iron-Deficiency Anemia. Iron-deficiency anemia is common, occurring in approximately 20 to 25% of pregnancies in industrialized countries. Apart from chronically low or marginal iron stores in many women, diversion of maternal iron to the fetus for development of its own RBCs and iron stores and increased maternal demand for iron exacerbate the deficiency during pregnancy. Pregnant patients are also subject to other causes of iron-deficiency anemia, such as malnutrition, chronic underlying disease, and blood loss from the gastrointestinal or genitourinary tracts.

Anemia in pregnancy is defined by the World Health Organization as a hemoglobin (Hgb) concentration less than 11 g/dL. Because of physiologic dilution, this level may be slightly lower after the 25th week of gestation. Mild, dilutional anemia (Hgb between 9 and 11 g/dL) confined to the later stages of pregnancy has little impact on obstetric outcomes.24 On the other hand, severe anemia (<6 to 7 g/dL) and non-dilutional anemia occurring early in pregnancy are associated with preterm delivery and low birth weights.24-26 The diagnosis of iron-deficiency anemia is most accurately made in the very early stages of pregnancy because serum ferritin, the preferred test, is affected by the dilutional effect of increased plasma volume occurring later in pregnancy. After the first trimester, other blood tests performed in combination may be necessary. The use of RBC indices is not a reliable screening tool because microcytosis and hypochromia are not reliably present in pregnant patients.

Iron supplementation to increase maternal iron stores (see Table 177-1) is indicated in women with iron deficiency even though it remains unclear as to whether such therapy improves perinatal outcomes. Patients with an otherwise uncomplicated physiologic anemia can be expected to have good obstetric outcomes without therapy and do not require iron treatment. The use of prophylactic supplementation in women with normal Hgb (>11 g/dL) and normal iron stores (ferritin >20 μg/L) is controversial. A trial found that iron supplements for such women prior to 20 weeks of gestation did not reduce the prevalence of preterm delivery or development of anemia later in pregnancy but did result in an increase in birth weight.27 Another trial found that the incidence of both preterm delivery and low birth weight was reduced in women on prophylactic iron.28

Folate-Deficiency Anemia. Folate deficiency is one of a number of causes of megaloblastic anemia, a condition characterized by abnormal DNA synthesis and ineffective RBC production. The incidence of folate deficiency in pregnancy is low (4%) in developed countries but remains higher in other populations.29,31 The risk of developing folate deficiency is increased in patients with multiple gestations, preexisting malnutrition, hyperemesis gravidarum, malabsorption syndromes, and alcoholism. Use of certain antiepileptic medications also places women at increased risk for deficiency.

Iron-deficiency and folate-deficiency anemias often coexist, making the peripheral blood smear difficult to interpret. Measurement of serum and RBC folate levels is indicated in cases of suspected folate deficiency, but both have limitations. Serum folate is noted to exhibit a rapid response to folate intake, and low levels may normalize within days after a folate-rich meal. Serum folate is also affected by the hemodilution of pregnancy. RBC folate levels are more static and are indicative of folate status several months prior to analysis. RBC folate levels may be misleading in more acute cases and are affected as well by the increase in RBC production that occurs in pregnancy.

As is the case for iron deficiency, effects on the fetus depend on the degree of anemia, with the most significant complications being neural tube defects (NTDs) and preterm delivery.32-34 Folate supplementation reduces the risk of NTDs,32,33 and oral folate supplementation with 0.4 to 1.0 mg daily is routinely recommended during pregnancy and prior to conception.34 Women at higher risk for NTDs (e.g., NTDs in prior pregnancy) are advised to take higher doses of folate at 4 mg daily.35

Sickle Cell Anemia. Sickle cell disease (SCD) is one of the major sources of maternal and fetal complications in the United States. The details of the pathophysiology and genetics of SCD are discussed in Chapter 119, but it is useful to review the most common phenotypes that affect pregnancy. The sickle gene can be homozygous (hemoglobin SS or SCD), and this form of the disease is responsible for most pregnancy complications. The sickle gene can also be heterozygous with normal hemoglobin A (sickle cell trait or hemoglobin SA), in which case symptoms are rare except under extreme environmental conditions. The hemoglobin S can also be heterozygous with a large number of abnormal hemoglobins such as hemoglobin C, several variants of thalassemia, and other rare hemoglobin variants, and each variant has its own complication profile. Of these, the most relevant in terms of pregnancy complications is hemoglobin SC.

Patients with SCD are subject to many chronic medical problems secondary to a variety of pathophysiologic mechanisms, including sickling of RBCs, anemia, immunosuppression caused by autosplenectomy, and the need for repeated transfusion. Median life expectancy is in the fifth decade for both sexes affected by SCD, and female fertility is generally unaffected, so it is likely that the emergency physician will encounter pregnant patients with the disease. Reported maternal complications in patients with SCD include preterm labor, premature rupture of membranes, maternal infections, more frequent pain crises, and an increased need for cesarean delivery.36,37 Despite these complications, the maternal mortality rate is less than 1% with current treatment.37

SCD also results in adverse effects on the fetus (see Table 177-1). Placental infarction is common, with small-for-gestational-age and low-birth-weight infants resulting from placental insufficiency.38 A high rate of fetal loss has been noted in the past, although a recent study found no increase in the rate of perinatal death.37 An incidental complication is that the Kleihauer-Betke test to distinguish fetal from mater-
nal blood will yield false-positive results because of the persistence of hemoglobin F in the mother.

Management of SCD during pregnancy is similar to that of the nonpregnant patient (see Table 177-1). Folate supplementation is standard even in the nonpregnant state because of the increased turnover of RBCs, although the recommended daily dose of folate increases to 4 mg during pregnancy. Supplemental iron is controversial because of the potential for iron overload. The need for therapy is best determined by the appropriate specialists after a complete analysis of relevant hematologic parameters. Prophylactic transfusion to achieve a predetermined hemoglobin level has not been found to improve pregnancy outcomes, although it may reduce the number of acute pain crises. Transfusion is reserved for patients with symptomatic anemia, cardiopulmonary instability, acute chest syndrome, and preeclampsia and possibly for patients with increasingly frequent pain crises. It is also used preoperatively for anticipated blood loss in patients undergoing cesarean section. Hydroxyurea is not recommended for use in pregnancy because of potential teratogenicity.

### Neurologic Disorders

#### Epilepsy

Epilepsy is the most common neurologic complication of pregnancy but remains relatively rare, affecting less than 1% of all gestations. Epilepsy refers to a broad spectrum of seizure disorders that range from relatively benign and infrequent seizures to a disabling condition with daily, poorly controlled generalized convulsions; therefore, care must be individualized. Management of epilepsy during pregnancy must balance the risk of increased frequency and duration of seizures to both the mother and the fetus against the teratogenic risks of antiepileptic medications (AEMs).

The effect of pregnancy on epilepsy is variable. Most (65%) epileptic patients experience no change in their seizure frequency, whereas 20% experience more frequent seizures and 15% experience less frequent events. A decrease in plasma drug concentrations is expected with the older AEMs due to alterations in the plasma volume, protein binding, and renal clearance that occur in pregnancy. In addition, some patients engage in voluntary noncompliance with medications to avoid teratogenic effects on the fetus. Data for the “newer” agents are less robust, but decreased drug concentrations also occur with lamotrigine, oxcarbazepine, and levetiracetam.

The primary adverse fetal complication in these pregnancies is congenital malformations. Of primary concern is the risk of NTDs with valproic acid and carbamazepine and facial clefts/cardiac anomalies with phenytoin and the barbiturates. There is a two- or threefold increase in the incidence of serious congenital malformations in offspring of epileptic mothers taking these drugs, and the risk is even higher if the mother is taking more than one agent. Controversy exists regarding whether infants of epileptic patients not taking AEMs have an increased incidence of congenital malformations compared with the general population. Studies comparing these infants with infants born to mothers without epilepsy noted a similar incidence of malformations. Data are limited, but preliminary results suggest that the newer agents also have a rate of congenital malformations similar to the general population.

Care should be provided by specialists in high-risk obstetrics and neurology disciplines; however, emergency physicians may be forced to confront this problem in several clinical scenarios—the pregnant patient with a first-time seizure or status epilepticus and the patient with epilepsy who is found to be pregnant.

#### New-Onset Seizure

Pregnant patients may seek treatment for idiopathic new-onset seizures; however, drug toxicity or withdrawal, head injury, meningitis, stroke, and eclampsia should be considered as possible causes. The most important of these is eclampsia. Patients in the immediate postictal phase often manifest hypertension resulting from massive sympathetic discharge, and even those with normal pregnancies may have mild edema of the lower extremities. Consequently, urinalysis should be performed to search for proteinuria, which may be the only differentiating factor in the initial assessment of these patients. After a period of observation, elevated blood pressure in the noneclamptic patient will likely revert to normal. If the patient remains hypertensive or manifests other signs of eclampsia, magnesium sulfate and other agents are indicated to prevent further seizures and to control blood pressure. In patients who do not manifest signs of eclampsia, investigation of the cause of the seizure should proceed as with the nonpregnant patient (see Chapter 100).

#### Status Epilepticus

Any potential seizure etiology, including eclampsia, may result in status epilepticus. Despite this, status epilepticus in pregnancy is relatively rare, and limited data are available regarding its occurrence and therapy. Observations from a pregnancy registry note that status epilepticus may occur at any time during gestation and even at delivery. It may also occur in patients who have been seizure-free throughout their pregnancy. Older reports note a high fetal and maternal mortality, but recent data support a much lower complication rate.

The risk of untreated status epilepticus to both the mother and the fetus clearly outweighs the potential for adverse teratogenic effects, and standard resuscitative measures as well as drug therapy are indicated. Continuous fetal monitoring should be instituted as soon as possible and the mother positioned in the left lateral decubitus position to avoid the supine hypotensive syndrome.

**Pregnant Epileptic Patient.** Patients with epilepsy coming to the emergency department for unrelated reasons may be found to be pregnant. Although no immediate change in their therapeutic regimen needs to be made, these patients should be advised of the potential risk of AEMs in pregnancy and be referred to appropriate specialists. Unintentional pregnancy is seen even in patients taking oral contraceptives because AEMs can cause increased clearance of these medications, thereby reducing their efficacy.

There are significant obstetric complications related to prolonged seizure activity, and long-term treatment with an AEM for most patients with seizures is warranted (see Table 177-1). Patients who have nonconvulsive seizure disorders or who are seizure-free for a sufficient period prior to conception are candidates for nonpharmacologic observation, but this decision should be deferred to the patient’s primary physician or neurologist. Because phenytoin, carbamazepine, valproate, and possibly other AEMs interfere with folate metabolism, oral supplementation with at least 0.4 mg/day is recommended for all women of childbearing age taking these drugs. Higher doses are recommended for women using valproic acid and carbamazepine, which are known to cause NTDs. Enzyme-inducing AEMs such as carbamazepine, phenytoin, and phenobarbital have been reported to cause neonatal vitamin K deficiency and hemorrhagic complications. It has been recommended that mothers taking these certain AEMs be given oral vitamin K during the last month of gestation, but data indicate that the actual risk of hemorrhage is low and possibly related to prematurity.
Multiple sclerosis (MS) affects approximately 400,000 Americans and is twice as common in women as in men. The peak age at onset is 20 to 35 years of age, which overlaps peak childbearing years. The disease is characterized by intermittent episodes of central nervous system demyelination with consequent neurologic impairment that follows a relapsing-remitting course. Progressive neurologic deficits and permanent disability develop in certain patients.

The impact of pregnancy on the course of MS has been closely studied in various cohorts of women, and a pattern has emerged. Like other autoimmune diseases, the frequency and severity of exacerbations of MS improve because of the immunosuppressant effects of pregnancy. This effect is most pronounced in the third trimester. During the 3 months after delivery, the rate of relapse increases and then returns to the prepregnancy baseline. Pregnancy does not seem to have any significant long-term adverse effects on disease progression. On the other hand, children of parents with MS have an increased susceptibility to develop MS, reflecting at least a partial genetic component to the disease.

Maternal relapse rate is unaffected by epidural anesthesia, and decisions regarding anesthesia should be based solely on obstetric considerations. Labor may be complicated by fatigue and uncoordinated voluntary motor activity in pushing, but generally pregnancies in these patients progress without undue complications.51

Spinal Cord Injury

Because spinal cord injury (SCI) occurs mainly in young people and usually does not impair fertility, there is a relatively large population of paraplegic and quadriplegic patients who become pregnant. Although many of these pregnancies are uneventful, these patients are at risk for certain complications.

The incidence of urinary tract infection is increased as a result of neurogenic changes and the need for catheterization. These infections may progress to pyelonephritis during pregnancy, with the subsequent increased risk of fetal loss, prematurity, and maternal sepsis. The increased coagulability of pregnancy combined with chronic immobilization results in an increased incidence of venous thrombosis and pulmonary embolus.

A unique problem in the patient with SCI is the detection of the onset of labor, which may be painless and precipitous. Patients with spinal cord lesions below T10 to T12 have an intact uterine nerve supply and will experience labor pains; however, with lesions above T10, labor may be imperceptible or experienced as only mild abdominal discomfort. In addition, 85% of patients with high lesions (above T5 to T6) experience potentially life-threatening autonomic dysreflexia. This manifests as severe paroxysmal hypertension, headache, tachycardia, diaphoresis, piloerection, mydriasis, and nasal congestion. Because the response is not specific to labor and may be precipitated by distention of bowel or bladder, other causes must be pursued as well. Pregnant patients with SCI who have these symptoms should be assessed for cervical dilation and have uterine contractions monitored. Emergency department treatment is directed at restoring normal blood pressure with nitroprusside, nitroglycerin, or hydralazine. Definitive therapy is with regional anesthesia. Both spinal and epidural anesthesia obliterates and prevent this response and should be used as soon as possible during labor for all women with SCI. Because of the difficulty in detecting labor, pregnant patients with SCI are sometimes admitted for observation near term.

Renal Disorders

Several alterations in renal hemodynamics occur during pregnancy. Both the glomerular filtration rate (GFR) and effective renal plasma flow increase by 30 to 50% compared with the nonpregnant state. Because no substantial alterations are present in the production of creatinine or urea nitrogen, levels of these solutes decrease from low normal nonpregnant values of 0.7 and 12.0 mg/dL to 0.5 and 9.0 mg/dL, respectively. Therefore, blood urea nitrogen and creatinine levels considered normal in nonpregnant women (creatinine > 0.8 mg/dL and blood urea nitrogen > 12 mg/dL) indicate underlying renal impairment and warrant further investigation.

The primary factors that determine how renal disease affects pregnancy outcome are the degree of underlying dysfunction...
and the presence of hypertensive disorders. In general, patients with mild insufficiency (creatinine < 1.4 mg/dL) and no hypertension can expect good pregnancy outcomes and preserved renal function. On the other hand, patients with moderate to severe renal dysfunction have a much higher risk of further decline in renal function as well as adverse obstetric outcomes, including preeclampsia, placental abruption, fetal loss, preterm delivery, low birth weight, and an increased need for cesarean section. 55-57 Worsening of underlying renal function is more likely in patients with decreased GFR who also have associated proteinuria and/or hypertension. 56-58 Because worsening renal function is manifested by hypertension and proteinuria, differentiation from preeclampsia can be difficult. In this setting, it is best to treat the patient for presumed preeclampsia with the caveat that magnesium administration be performed judiciously based on serum magnesium levels.

Pregnant women with chronic renal failure require aggressive and timely management to optimize their chances for a successful gestation without causing further deterioration in renal function. Baseline renal function studies are done early in pregnancy and then reassessed every 4 to 6 weeks. Evidence of renal function deterioration or the development or exacerbation of hypertension warrants admission for specialized inpatient care. Hemodialysis is indicated for creatinine levels greater than 3.5 to 5 mg/dL. In patients undergoing dialysis, sessions are more frequent and more prolonged to minimize azotemia. 59

Metabolic and Endocrine Disorders

Diabetes

Three types of diabetes are involved in pregnancy: type I, or insulin-dependent diabetes mellitus (IDDM); type II, or non-insulin-dependent diabetes mellitus (NIDDM); and gestational diabetes mellitus (GDM). Although NIDDM is sometimes considered a more benign form of disease, the risk of malformations is the same for both NIDDM and IDDM. 60,61 Maternal and fetal complications relate more to inadequate glycemic control as well as the presence of vascular complications or severe renal insufficiency rather than to the type of diabetes. All pregnant patients with diabetes are considered “brittle” and require regular follow-up by appropriate specialists. In addition, all patients, including those with GDM, should perform routine self-monitoring of glucose.

Maternal Complications. The physiology of glucose regulation during pregnancy is complex. During the first half of gestation, the sensitivity to insulin increases as a result of increased circulating estrogen. When combined with emesis, increased use of glucose by the placenta and fetus, and a decrease in hepatic glucose production, hypoglycemia occurs more easily. Consequently, patients with IDDM are at risk for severe hypoglycemia during early pregnancy and insulin dosage should be decreased. During later gestation, however, there is progressive insulin resistance that peaks during the third trimester and then falls again during labor and the immediate postpartum period. Pregnancy also predisposes to ketosis, and this effect is exacerbated in the setting of emesis. Specific adverse pregnancy-related outcomes are more common and include preeclampsia, preterm delivery, and the requirement for cesarean delivery. 62,63

The effects of pregnancy on underlying diabetes vary depending on the organ system. The data are limited, but pregnancy is not advised for diabetic patients with significant coronary artery disease because of the cardiovascular demands of pregnancy and the high mortality of AMI during pregnancy. 62 Patients with diabetic nephropathy are at increased risk for preeclampsia and the subsequent requirement for preterm delivery. 62 The renal effects of pregnancy depend on the severity of underlying disease. Patients with mild to moderate renal dysfunction do not seem to experience permanent disease progression. On the other hand, women with more severe renal dysfunction are at increased risk for progression to end-stage disease. 56,62 Retinopathy may worsen acutely during pregnancy, especially in patients with high HbA1c and hypertension and in the setting of aggressive control of hyperglycemia. 62,64 Laser therapy of preexisting retinopathy is recommended prior to conception. 60,62 Autonomic neuropathy does not accelerate during pregnancy, 64 but the combination of hyperemesis gravidarum and gastroparesis often causes problems. Frequent vomiting results in dehydration and inadequate intake of food that can result in hypoglycemic episodes if the insulin dosage is not adjusted accordingly. 60

Diabetic ketoacidosis (DKA) occurs in up to 10% of diabetic patients during pregnancy and may represent the initial presentation of diabetes. DKA is most commonly seen in patients with IDDM but also complicates pregnancies in women with NIDDM and GDM. 62 Common precipitating events include the typical factors seen in nonpregnant patients, such as insulin noncompliance and infection. Other pregnancy-specific factors are hyperemesis, use of beta-mimetic medications for tocolysis, and use of corticosteroids to hasten fetal lung maturity. The serum pH may be deceptively normal in a pregnant patient with DKA because the initial pH tends to be higher in pregnancy due to physiologic hyperventilation. Loss of gastric acid through vomiting will also counteract the metabolic acidosis of diabetic ketoacidosis. In addition, serum glucose may be only moderately elevated because the fetus continues to secrete insulin and use glucose. Maternal mortality is rare in appropriately treated DKA. Fetal mortality rates are relatively high, ranging from 10 to 35%. 62

Fetal Complications. Diabetes has many deleterious effects on the fetus (see Table 177-1). The rate of congenital malformations in patients with prepregnancy diabetes is increased three- to fourfold compared to the nondiabetic population, with anomalies being more likely in pregnancies with poor glycemic control. 62,63,65 Glucose crosses the placenta, and prolonged fetal exposure to maternal hyperglycemia induces fetal pancreatic hyperplasia and high insulin production. Elevated insulin levels in turn promote fetal growth, resulting in macrosomia. Conversely, preeclampsia and placental infarction secondary to vascular disease may result in impaired fetal development. 62,63 After delivery, continued high insulin secretion in the absence of a maternal glucose supply results in a significant rate of neonatal hypoglycemia. Because these infants are more likely to be preterm, hyperbilirubinemia and respiratory problems are also more frequent. 62,63 Long term, it is likely that poor metabolic control during pregnancy leads to an increased risk of impaired glucose tolerance, obesity, and NIDDM in affected offspring. 60,62,64,65

Management. Treatment of NIDDM and IDDM requires individualized and carefully adjusted insulin administration with the goal to maintain strict glycemic control while avoiding hypoglycemia. Ideally, HbA1c values should not be greater than 6% (see Table 177-1). 60,62 Frequent self-monitoring is recommended, and these patients should also have frequent office visits with their practitioner throughout the duration of pregnancy. 62 It is preferable to achieve glycemic control prior to conception in order to minimize the risks of malformations and other complications. 60 Treatment of DKA does not differ from treatment given in the nonpregnant state except that fetal viability and well-being should be assessed.

The timing and mode of delivery depend on whether there exist obstetric or maternal complications. In the absence of
suspected problems, vaginal delivery at term is recommended. Elective delivery is indicated in the setting of poor metabolic control, significant diabetic complications, and fetal macrosomia with suspected birth weight greater than 4500 g. Delivery is timed to avoid fetal growth into the macrosomic range while allowing for sufficient fetal lung maturity. If corticosteroids are administered, very close glucose monitoring is required because insulin requirements are likely to increase. Progression beyond term is not recommended.

**Gestational Diabetes**

GDM is defined as glucose intolerance that begins (or is first detected) during pregnancy. As the incidences of both NIDDM and IDDM have increased, so has that of gestational disease. GDM has little impact on perinatal mortality if detected and addressed; however, untreated disease increases the likelihood of fetal macrosomia and adverse perinatal outcomes. GDM is also a risk factor for the subsequent development of nongestational diabetes. Patients at increased risk for NIDDM include those with obesity, whereas patients with evidence of islet cell immunity are at risk for development of IDDM.

The exact means of screening for GDM is controversial, but all pregnant women should undergo some form of screening, even if it is accomplished simply by obtaining a clinical risk profile. The American Diabetes Association advocates selective laboratory assessment in patients at high risk for GDM. This group includes patients older than 25 years; certain high-risk ethnic groups; and patients with obesity, known first-degree relatives with diabetes, a personal history of diabetes or glucose intolerance, and a personal history of poor pregnancy outcome. A positive screening test at 24 to 28 weeks of gestation via measurement of serum glucose 1 hour after a 50-g oral load is an indication for a formal 3-hour glucose tolerance test.

The majority of patients with GDM achieve metabolic control with dietary therapy. Traditionally, insulin administration is indicated if dietary control is unsuccessful (see Table 177-1). Standard practice is to avoid oral medications because they cross the placenta and have the potential for teratogenicity. However, studies comparing insulin with glyburide in GDM found that the latter provided similar glycemic control without an increase in adverse pregnancy outcomes. Preliminary investigations of metformin have found this agent to be safe for use in pregnancy, but further study is recommended prior to its widespread use. There are very limited data for other oral medications.

**Thyroid Disorders**

The peak incidence of thyroid disease is in women of childbearing age. Both hypoactivity and hyperactivity lead to obstetric complications and warrant specific therapy. As with other organ systems, there are physiologic changes in thyroid function that occur in normal pregnancies. Human chorionic gonadotropin (hCG) is structurally similar to thyroid-stimulating hormone (TSH) and stimulates the thyroid gland. As a result, women with normal pregnancies may experience a temporary suppression in TSH production and slightly lower TSH levels during the first trimester, which mirrors the high circulating hCG levels seen at this gestational period. This hCG-mediated effect may lead to a transient hyperthyroidism if hormone levels are markedly increased. Estrogen increases the amount of thyroid hormone binding proteins, which ultimately leads to an increase in the amount of total T₄ and T₃ even though free hormone levels remain normal. After 10 to 12 weeks of gestation, the fetus makes its own thyroid hormone but still requires placental transport of iodine and adequate maternal intake of this element (200 µg/day).

**Hyperthyroidism**

The most common cause of hyperthyroidism is Graves’ disease, in which autoimmune thyroid-stimulating immunoglobulin G results in increased production and release of thyroid hormone. Because the symptoms of hyperthyroidism resemble the physiologic changes expected during pregnancy in many respects, the diagnosis may not be immediately evident. Patients with Graves’ disease have disease-specific findings, including a diffusely enlarged, soft, mildly tender thyroid gland; exophthalmos; and dermopathy. Other symptoms, such as dyspnea, heat intolerance, hyperemesis, tachycardia, palpitations, systolic flow murmurs, increased appetite, and fatigue, are common to both conditions, making clinical diagnosis difficult. In cases of suspected hyperthyroidism, thyroid function studies are indicated and will confirm the presence of disease.

There are several obstetric concerns for both mother and the fetus in the setting of untreated hyperthyroidism (see Table 177-1). Thyroid storm is the most serious manifestation of the disease. It may be precipitated by stressors such as infection and delivery, and it manifests with fever, dysrhythmias, myocardial dysfunction, mental status changes, and circulatory collapse. In addition to the more general complications stemming from thyroid hormone excess, Graves’ disease places the fetus at risk for autoimmune-mediated thyroid dysfunction via placental transfer of maternal thyroid-stimulating immunoglobulins (TSIs). Up to 17% of neonates of mothers with Graves’ disease and positive TSI values have transient hyperthyroidism lasting 3 to 12 weeks. The condition gradually clears as maternal antibodies are metabolized. Manifestations are potentially severe and include irritability, tachycardia, goiter, cardiomegaly, congestive heart failure, premature craniosynostosis, low birth weight, and failure to thrive. These infants also have an increased mortality rate, so the condition must be recognized promptly and treated aggressively with typical therapies.

The mainstay of treatment of hyperthyroidism (see Table 177-1) consists of antithyroid drugs. Propylthiouracil has traditionally been preferred over methimazole because of an increased potential for adverse congenital drug effects from the latter. Both drugs cross the placenta and can cause fetal hypothyroidism. Consequently, maternal thyroid function should be assessed periodically during pregnancy with the goal of keeping free thyroxine in the high normal range. Most patients respond to pharmacologic manipulation, although thyroidectomy may be considered in severe cases. Use of iodine-131 radionuclide to ablate the maternal thyroid is contraindicated because it will also destroy the fetal thyroid gland.

Additional therapy with beta-blockade to mitigate the hemodynamic effects of sympathetic stimulation may be required in certain cases pending adequate disease control with antithyroid medications. In the nonpregnant patient, iodides may be used to transiently block the release of stored T₄ from the thyroid gland and inhibit organification of iodide. However, the fetal thyroid is extremely sensitive to iodide, which may result in neonatal goiter and hypothyroidism. Therefore, iodide is considered class D in pregnancy, and its use should be reserved for severe cases with duration of therapy limited to a period of days. As with other autoimmune conditions, transient improvement of Graves’ disease during pregnancy is common, with rebound and clinical deterioration occurring after delivery.
Postpartum Thyroiditis

Postpartum thyroiditis (PPT) is a common but relatively benign condition that develops in approximately 7% of parturients within 9 months of delivery. Patients typically experience transient hyperthyroidism, transient hypothyroidism, or transient hyperactivity followed by transient hypoactivity. Symptoms are typical for type of impairment, although they are often mild. Pharmacologic treatment may be required; however, the need for medication seems to be confined to those patients with hypothyroidism. Occasionally, patients with transient hyperthyroidism require beta-blockers, but antithyroid drugs are not helpful because pathophysiology relates to release of preformed thyroid rather than excess thyroid hormone production. Approximately 30% of patients with PPT develop permanent thyroid failure, and this percentage is increased to more than 50% if one considers just the patients with postpartum hypothyroiditis.

Hypothyroidism

The most common cause of hypothyroidism is Hashimoto’s thyroiditis. Overt hypothyroidism is often associated with infertility, so most cases seen during pregnancy are less severe or subclinical forms or occur in patients already undergoing levothyroxine therapy for known disease. Undiagnosed subclinical hypothyroidism may manifest during pregnancy as physiologic adjustments result in a greater requirement for thyroid hormone production. In addition, iodine deficiency may be exacerbated by pregnancy because renal losses of iodine increase as the glomerular filtration rate increases and as the fetus diverts iodine for its own thyroid hormone synthesis.

Approximately 3 to 5% of women of childbearing age have subclinical hypothyroidism and, unfortunately, these patients may remain asymptomatic. When signs and symptoms do occur, they are identical to those in the nonpregnant state. Myxedema coma is extremely rare but must be considered along with other causes of coma in a pregnant patient.

As with hyperthyroidism, there is an increased incidence of adverse maternal and fetal effects (see Table 177-1). The majority of patients who are already undergoing treatment for hypothyroidism will require an increased dosage of levothyroxine during pregnancy, and close monitoring of thyroid function is recommended as soon as possible after conception.

Tuberculosis

Acquisition and presentation of tuberculosis is unchanged during pregnancy. However, the effect of tuberculosis on pregnancy is unclear. Some studies reveal a significant increase in gestational complications (see Table 177-1), but these outcomes are likely significantly influenced by the site of disease and specifics of treatment or lack thereof. One study found no significant increase in gestational complications in 111 pregnant patients with properly treated tuberculosis.

Complications are more likely in patients with inadequate or delayed treatment, delayed diagnosis, and extrapulmonary (extranodal) tuberculosis. Neonatal tuberculosis acquired via exposure to undiagnosed and untreated active disease places infants at significant risk for acquiring tuberculosis during the first year of life, with significant mortality. In addition, congenital tuberculosis is possible after the fetus becomes infected via the placenta or aspiration of infected amniotic fluid. The latter is rare if the mother has received appropriate therapy.

Current recommendations are to administer a tuberculin skin test early in pregnancy to all patients at high risk for disease and to obtain a chest radiograph if the purified protein derivative (PPD) skin test is positive or if the patient’s signs and symptoms suggest tuberculosis. Universal screening should be considered in urban areas with a high prevalence of disease. Definitive treatment varies depending on the duration of PPD positivity and whether the patient has active disease (see Table 177-1). Isoniazid, ethambutol, and rifampin in their usual doses have not been shown to be teratogenic to human fetuses and are acceptable during pregnancy. On the other hand, streptomycin causes fetal ototoxicity, and little is known about the safety of other second-line agents during pregnancy. These less commonly used agents should be avoided except in the case of multidrug-resistant disease.

Human Immunodeficiency Virus and Acquired Immunodeficiency Syndrome

The human immunodeficiency virus (HIV) is one of the leading health problems in pregnancy. In 2005, 27% of reported cases of HIV/acquired immunodeficiency syndrome (AIDS) in the United States were in women, with the majority being in women of childbearing age. Estimates of the seroprevalence of HIV in pregnant women vary on a regional basis. In the United States, the overall prevalence is low but also varies depending on the population, with increased rates seen in inner-city and other high-risk populations.

The mechanism of vertical transmission is multifactorial. The majority of cases are thought to occur during delivery through exposure to maternal blood and secretions; other infants are likely infected in utero or via breast-feeding. Various factors influence the rate of transmission. The most important is maternal viral load, although infection can occur even with maternal HIV RNA greater than 1000 copies/mL. Other contributing factors for transmission include vaginal infections, intravenous drug use, low birth weight, and prolonged rupture of membranes. Vertical transmission...
The incidence of primary and secondary syphilis among females in the United States steadily declined between 1990 and 2004 but increased during 2005 and 2006, with a current rate of 1 case per 100,000 women.146 Fortunately, the incidence of congenital syphilis (CS) is declining, but the disease remains a concern among those patients without access to adequate prenatal care and prenatal syphilis screening.177

Syphilis causes numerous gestational complications (see Table 177-1), but its most significant sequela is CS. This syndrome is characterized by clinical abnormalities such as hepatosplenomegaly, osteochondritis, jaundice, rash, lymphadenopathy, rinitis, Hutchinson’s teeth, and anemia. Perinatal mortality for cases occurring from 1992 to 1998 was 6.4%.118 If untreated, vertical transmission rates are high but can be reduced significantly with appropriate penicillin therapy.119 Screening for all pregnant patients is indicated at the first prenatal visit and again in the early third trimester and at delivery for high-risk patients.104 Either Venereal Disease Research Laboratory (VDRL) or rapid plasma reagin (RPR) testing can be used to detect nontreponemal antibody. Pregnancy may cause false-positive results for nontreponemal studies, so confirmation using specific treponemal tests is indicated for a positive VDRL or RPR study. Patients with latent syphilis and those whose titers fail to respond to therapy should undergo cerebrospinal fluid analysis to screen for tertiary syphilis. In addition, fetal ultrasonography prior to the 20th week of gestation is indicated to assess for abnormalities consistent with CS.

Treatment is identical to that given to nonpregnant patients using benzathine penicillin G (see Table 177-1).104 Penicillin-allergic patients should undergo skin testing and desensitization if the skin test result is positive because alternative therapy is not reliably effective in preventing congenital syphilis.104 Treatment failures are rare with appropriately administered penicillin but do occur. Failures leading to CS are more likely in mothers with secondary syphilis, high VDRL levels, and an interval from treatment to delivery of less than 30 days. They are also more likely in the setting of preterm delivery.119,120

Hepatitis

Hepatitis B. The prevalence of hepatitis B virus (HBV) infection among pregnant women varies depending on the population studied. In U.S. urban areas, 0.14 to 5.79% of pregnant women are positive for HBsAg, with Asians having the highest seroprevalence.121 The rate of vertical transmission depends on the acuity of maternal infection and when during the gestation it occurs. Perinatal transmission approaches 90% in mothers who are seropositive for HBsAg and HBeAg and is also more likely if the mother has acute infection during the third trimester or first few months postpartum or if she is a chronic carrier.104,122 Of infants who develop HBV infection, up to 90% become chronic carriers as adults and are at risk for complications such as cirrhosis and hepatocellular carcinoma.104

Routine screening for HBV during early pregnancy is recommended because treatment with hepatitis B immunoglobulin and hepatitis B vaccine is very effective in reducing the rate of vertical transmission.122,123 Treatment failures do occur in the setting of maternal seropositivity for HBeAg and HBV DNA.124 Women at risk for sexually transmitted disease (STD) and women with hepatitis should be retested at delivery.104 Vaccination against HBV is currently recommended for all infants in the United States. The treatment schedule and the need for additional therapy with immunoglobulin vary depending on maternal seropositivity. Infants of HBsAg-positive mothers should receive hepatitis B immunoglobulin and the first dose of vaccine within 12 hours of birth. Two additional doses of vaccine are administered at a later date. Pregnancy is not a contraindication to either therapy. All HBsAg-negative gravidas at risk for STDs or who are seeking STD treatment should receive the vaccine.104,124 Pregnant patients who are
exposed to HBV should receive both hepatitis B immunoglobulin and vaccine.\textsuperscript{122}

**Hepatitis C.** As with HBV, the prevalence of hepatitis C infection among pregnant women varies depending on the population, ranging from less than 1% to approximately 5%. Vertical transmission is rare in mothers with anti-hepatitis C antibodies and no circulating hepatitis C virus (HCV) RNA.\textsuperscript{125,126} However, perinatal transmission is significantly increased by the presence of HCV viremia, occurring in approximately 4 to 6% of cases. The transmission rate is even higher in the setting of co-infection with HIV.\textsuperscript{125-127} Unfortunately, there is little definitive data regarding the use of cesarean delivery to prevent HCV transmission.\textsuperscript{129} No available vaccine exists to prevent hepatitis C, although testing of potentially infected neonates is advised to identify those at risk for chronic hepatitis.

**Inflammatory Disorders**

Rheumatic diseases or collagen vascular diseases are characterized by sterile inflammation in multiple anatomic sites. The most common rheumatic diseases encountered in pregnancy are systemic lupus erythematosus (SLE) and rheumatoid arthritis (RA). Patients with collagen vascular disease may have preexisting cardiovascular or renal compromise and may not tolerate the increased intravascular volume and other physiologic changes that occur during pregnancy. The following discussion focuses on SLE, which is the rheumatic disease responsible for the majority of gestational complications. Most of the treatment guidelines for SLE are relevant to other rheumatologic disorders as well.

**Systemic Lupus Erythematosus**

SLE primarily affects women of reproductive age, and fertility is usually unaffected. The disease course during pregnancy is a matter of controversy, but analyses indicate that acute flares occur in less than one third of patients in clinical remission at the time of conception. These flares tend to be mild and involve the skin and musculoskeletal system.\textsuperscript{129,130} The gestational effects of SLE also depend on the underlying severity,\textsuperscript{131} and it is best for women to achieve good disease control prior to pregnancy. Many patients have acceptable outcomes, but lupus pregnancies are associated with an increased rate of complications, including hypertensive disorders, preterm delivery, intrauterine growth retardation, fetal loss, and need for cesarean section.\textsuperscript{129,130,132,133} The risk of preeclampsia is markedly increased in patients with preexisting lupus nephritis.\textsuperscript{134,135} As with other renal disease, increasing proteinuria warrants a careful evaluation to distinguish between lupus glomerulonephritis and preeclampsia. The presence of abnormal urine sediment, increasing titers of anti-DNA antibody, and decreasing levels of C3 and C4 point to lupus nephritis.\textsuperscript{129}

Numerous other organ systems in addition to the kidneys are involved in SLE, and differentiation from pregnancy-related changes may be difficult. Mild thrombocytopenia occurs in normal pregnancies and is also common in patients with SLE, although the clinical significance varies from patient to patient. Anemia is a frequent complication of lupus and magnifies the normal dilutional anemia of pregnancy. Various musculoskeletal and cutaneous symptoms associated with pregnancy, such as arthralgias and facial and palmar erythema, can also resemble active SLE. In addition, preexisting lupus rashes become more erythematous because of the increased cutaneous blood flow during pregnancy. Neurologic disease in SLE may manifest as psychosis, seizures, chorea, or peripheral neuropathy. The incidence of these complications is low during pregnancy, although the occurrence of seizures in late pregnancy in patients with coexistent hypertension and renal insufficiency may pose a diagnostic dilemma between the neurologic effects of SLE and eclampsia.

**Other Rheumatologic Diseases**

Rheumatoid arthritis is characterized by chronic, destructive, symmetrical joint inflammation. Less common manifestations include the development of subcutaneous nodules, neuropathy, pleuritis, and vasculitis. Systemic symptoms, including weight loss, lymphadenopathy, and fatigue, are common. Because the median age at onset is later with RA, this disorder is seen less frequently than SLE in the pregnant population.\textsuperscript{132} Approximately two thirds of patients with RA experience an amelioration of symptoms during pregnancy, although often an exacerbation follows delivery.

Patients with other rheumatologic diseases, including scleroderma, Raynaud’s phenomenon, and polymyositis, tend to have good pregnancy outcomes in the setting of good disease control. Birth weights are lower in the offspring of these patients likely as a result of the underlying vasculopathy.\textsuperscript{136,137}

**Treatment**

The rheumatologic diseases are very similar with respect to the therapeutic approach. Corticosteroids form the basis of treatment for most disease complications and exacerbations. These drugs may result in a minimally increased risk of cleft deformities (data are inconclusive) but have not been found to have any other significant teratogenic effects and are considered relatively safe to use for disease control in these patients.\textsuperscript{9,10} Steroid use during pregnancy does have a dose-related effect on intrauterine growth retardation and predisposes the patient to GDM and hypertension, so close monitoring is advised.

Aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs) are also a mainstay of therapy in many patients with rheumatic diseases and may be used in pregnancy. There are potential adverse effects of aspirin and NSAIDs on gestation, including miscarriage when taken early in pregnancy and premature closure of the fetal ductus arteriosus, increased maternal hemorrhage, and prolongation of gestation and labor when taken later in pregnancy. There are also conflicting data regarding an increased risk for gastrochisis, cleft defects, and cardiac defects with NSAID use.\textsuperscript{138-140} If a true association exists, the risk for these anomalies remains extremely small in absolute terms. Use of these agents after 32 weeks of gestation should be avoided to minimize the risks of maternal and fetal hemorrhage and premature ductus closure.

Acute flares often require institution of cytotoxic drugs. Cyclophosphamide and methotrexate are contraindicated during the first trimester and should be used only in extreme circumstances because of their teratogenicity and abortifacient properties. Azathioprine has a much more favorable safety profile because of its use in renal transplant patients, and it is the cytotoxic agent of choice during pregnancy. Although the drug and its metabolites cross the placenta, it does not appear to have any major teratogenic effects.\textsuperscript{141} Cyclosporine also seems to lack teratogenicity and is an acceptable alternative to azathioprine.\textsuperscript{142}

The antimalarial agent hydroxychloroquine is also used in the treatment of SLE and RA. This medication has been found to be safe during pregnancy, and its use may allow for a decrease in corticosteroid dosage.\textsuperscript{143,144} In addition, patients who have been maintained on hydroxychloroquine prior to conception experience an increased rate of disease flares when the agent is discontinued.\textsuperscript{143}
The physiologic demands of pregnancy may cause previously occult medical conditions to become apparent.

The physiologic adjustments of pregnancy alter the normal ranges for certain laboratory values. The adjusted values need to be considered in interpreting results.

The possibility of pregnancy must be considered in the differential diagnosis of certain conditions, including new-onset seizures or status epilepticus (eclampsia), glucose intolerance (GDM), persistent vomiting (hyperemesis gravidarum), and thyroid disorders.

The immunosuppressive effects of pregnancy may cause temporary improvement in inflammatory and autoimmune conditions. This beneficial effect is lost in the postpartum period, resulting in exacerbations of asthma, thyroid disorders, and myasthenia gravis. Medication requirements can change drastically during pregnancy and the postpartum period.

Certain medical conditions in the mother result in neonatal complications requiring special resuscitative measures.

CHAPTER 178  Drug Therapy in Pregnancy

Rania Habal

■ PERSPECTIVE

The placenta was previously believed to act as a barrier, excluding toxins from the fetal circulation and protecting the fetus from environmental and pharmacologic exposures. In 1961, when an epidemic of amelia, a rare malformation characterized by an absence of limbs, was linked to the use of thalidomide during pregnancy, the vulnerability of the fetus to medications came into focus. Thalidomide was a sedative-hypnotic agent introduced in 1956. It immediately became popular in the treatment of nausea and vomiting during the first trimester of pregnancy, but in the years that followed, it was established that thalidomide was the agent responsible for the amelia/phocomelia epidemic. By the time thalidomide was withdrawn from the market, an estimated 5850 children were affected worldwide.1 Similarly, it took an epidemic of debilitating congenital anomalies and deaths in the children of fishermen in Minamata, Japan, to recognize the teratogenicity of environmental pollutants.2,3 Minamata disease was due to the ingestion of fish contaminated by methylmercury, an industrial by-product that was dumped into Minimata Harbor in the early 20th century. These two events sparked the development of numerous control agencies to oversee the safety of drugs in pregnancy and numerous environmental protection laws.

Thalidomide’s legacy continues to haunt physicians worldwide. Many physicians are reluctant to prescribe medications to pregnant women or to nursing mothers. However, only a few medications have been identified as teratogens, and medication use during pregnancy is extremely common. In a worldwide survey of more than 14,000 patients, the World Health Organization reported that more than 86% of women used at least one prescription drug while pregnant. In a similar survey in the United States, more than 80% of pregnant women reported using medications during pregnancy, with 30% using more than four drugs.4 The contribution of these substances to the incidence of birth defects is thought to be low, accounting for 1 to 3% of all live birth defects.5,6

The emergency physician must understand when the maternal benefit of prescribing a particular agent will outweigh any potential risk of fetal harm, and he or she must be able to discuss those risks and benefits with the patient.

■ PRINCIPLES OF DISEASE

Major birth defects affect 3 to 5% of all live births.6 Most are of unknown etiology, but 1 to 3% of these are thought to be due to pharmaceutical agents.5,6 A teratogen is any chemical, pharmacologic, environmental, or mechanical agent that can cause deviant or disruptive development of the conceptus.5,7 Included in this definition are physical malformations, growth retardation, fetal demise, and functional impairment.6 Although serious effects on the mother are identified immediately, a drug’s teratogenic effect may not be apparent for years. Malformations may range from subtle neurobehavioral effects to devastating physical deformities and physiologic effects, including death.5,7 Why one pregnancy would be affected and not another remains to be elucidated. Highly teratogenic medications seem to be few in number, estimated at well below 50 agents (Box 178-1).7,8

When examining the effects of substances on the outcome of pregnancy, it is important to keep in mind that the process of establishing the risk and safety of drugs in pregnancy is tedious and often flawed. For ethical reasons, few controlled prospective human studies analyzing the risk-benefit relationship for any given exposure are available. As a result, much current knowledge has been derived from case reports, case-controlled studies, or cohort studies, which are inherently weak in establishing a causal relationship,1,5–9 and from animal research. Knowledge extrapolated from animal models, although valuable in determining risk initially, is not always applicable to humans.1,5–9

In evaluating data on the relationship between an exposure during pregnancy and a particular outcome, a multitude of confounding factors make the determination of a causal link difficult. The genetic background of the fetus, the timing and duration of the exposure, environmental factors, the occurrence of multiple exposures and the presence of nutritional deficits, maternal illness, and illicit drug use all contribute to the outcome of pregnancy.1,5–9 In the presence of maternal illness, for example, the outcome of pregnancy may be related to the medical condition and not the medication, and separating the risks of an anomaly from the expected background risk may be difficult.

The study of teratogenicity is also hindered by several additional factors. First, the history of drug or environmental exposure is often obtained in retrospect, after 9 months of pregnancy and the delivery of an abnormal infant. By that time, significant recall bias may have been introduced, which may depend on the outcome of the birth.9 Second, because many pregnancies are spontaneously aborted before maternal knowledge that conception has occurred, the cited prevalence of drug-induced birth defects may not be accurate.5,6,8,9 Finally, as in the case of diethylstilbestrol, teratogenicity may not be appar-

Classification of Teratogenic Risk

To aid physicians in determining the teratogenic potential of a particular medication, the U.S. Food and Drug Administration (FDA) has published a classification system that assigns risk based on currently available human and animal studies and case reports. Drugs are assigned one of five letters—A, B, C, D, and X—depending on the strength of evidence for their safety or teratogenicity (Box 178-2). The FDA classification system has been criticized as oversimplistic and perhaps inaccurate because it relies on data that are generally of poor quality. In addition, using this classification, more than 90% of drugs approved in the United States between 1980 and 2000 were assigned an undetermined teratogenic risk. Furthermore, some clinicians believe that the classification system conveys the incorrect impression that there is a gradation of reproductive risk from exposure across categories (i.e., that risk increases from A to B to C to D to X) and that the drugs within a given category present similar reproductive risks. The FDA has acknowledged these problems, and in 2008 it proposed new rules regarding drug labeling during pregnancy and the elimination of the current ABCDX pregnancy categories. A number of clinical teratology resources, such as TERIS, REPROTOX, and REPRORISK (Shepard’s catalogue of teratogenic agents), are now available online. These databases assign teratogenic risk to drugs based on a consensus of opinion of an expert panel.

Drug Transfer across the Placenta

The degree to which the fetus is affected by a given pharmaceutical agent and the nature of that effect depend on multiple factors. The transport of maternal substrates to the fetus and of waste products from the fetus to the mother is established during week 5 of gestation. Drug transfer across the placenta occurs most commonly by simple passive diffusion or by protein transport. A thin layer of trophoblastic cells is all that separates maternal from fetal circulation. The degree to which a drug gains access to fetal circulation depends on molecular size, ionic state, lipid solubility, and the extent of protein binding. Drugs with a molecular weight of less than 5 kDa readily diffuse. Anionic forms diffuse through the lipid layer more readily than ionized forms. Free drug diffuses more readily than a drug that is bound to plasma proteins. Because fetal pH is slightly more alkalotic than maternal pH, weak organic acids (e.g., salicylate) may become ion trapped in the fetal circulation, increasing fetal exposure.

Drugs may affect the fetus through a variety of mechanisms. Some drugs may alter the availability of substrates, such as vitamins, glucose, oxygen, and amino acids, needed for normal nutrition and growth. Others may directly affect cellular growth and differentiation. The age of the fetus is crucial in determining the impact of any given exposure. During the time of organogenesis (days 21–56 of fetal life), the fetus is much more vulnerable to toxic insults. The major body organs are formed during this period, and exposure to a terato-
gen at this time may result in major anatomic defects. The central nervous system (CNS) develops over a longer period (10–17 weeks) so that later exposures may affect neurologic development and subsequent function. Exposure after the period of organogenesis may affect the growth and development of the fetus but does not have an impact on organogenesis; however, it most likely affects fetal growth.15,5,8

Drug Transfer during Lactation

For the most part, drugs and substances that are ingested or injected by the mother diffuse passively into milk and then back into the maternal circulation for excretion.14 The amount of drug diffusing into milk depends on many factors. Lipid-soluble and nonionic substances diffuse more readily, and highly protein-bound substances diffuse less readily.14 Whether a substance is concentrated in maternal milk or not, the neonate generally is able to detoxify it with no adverse effects, and only a few drugs pose a serious danger to a breast-feeding infant.14 The interruption of breast-feeding should not be advocated except in rare situations of known drug toxicity to the infant.15

Table 178-1 summarizes the compatibility of medications and their effects in pregnancy and lactation.

■ DRUG THERAPY DURING PREGNANCY

In general, the health of the fetus is directly related to the health of the mother. Physicians should never withhold lifesaving medications from pregnant patients because of a reported risk to the fetus and should resuscitate pregnant patients according to Advanced Life Support Guidelines. Physicians may also prescribe any agent that presents maternal benefits that outweigh the risks to the fetus. Included in this category are therapeutic medications for asthma, arrhythmias, status epilepticus, and HIV.

Analgesic Agents

Acetaminophen (paracetamol) is safe throughout pregnancy. It is widely used during pregnancy and has not been associated with an increase in the incidence of congenital malformations when therapeutic doses are used.16,17 Statements about its safety also apply to acute and chronic overdose conditions.18,19

However, there is an increase in the incidence of spontaneous abortion and fetal demise, especially when antidote treatment with N-acetylcysteine is delayed.18,20 Acetaminophen is safe during lactation because only a small amount is excreted into breast milk, and the amount that does get through is tolerated by the neonate’s sulfhydration pathway.15,16

Aspirin appears to be safe throughout pregnancy when used in small doses. Early studies of aspirin use during pregnancy linked it to an increased risk of perinatal and neonatal bleeding, increased risk of postmaturity, significant prolongation of labor, low birth weight, neonatal hypoglycemia, metabolic acidosis in the newborn, and neonatal death.16,17 However, in the Perinatal Antiplatelet Review of International Studies Collaboration (PARIS) study, low doses of aspirin were actually found to be beneficial and to reduce the risk of preeclampsia, prematurity birth, and adverse perinatal outcomes.23 Furthermore, a number of recent meta-analyses in humans failed to demonstrate a teratogenic effect to aspirin, although there was a trend toward a slightly increased incidence of gastrochisis when used in the first trimester.21,22

Non-aspirin NSAIDs should be avoided in the first and third trimesters but are considered safe in the second trimester. Use of NSAIDs in the first trimester has been associated with a small increase in cardiac defects, oral clefts, and gastrochisis.16,17,24 Use of NSAIDs at or near term has been associated with premature closure of the ductus arteriosus, periventricular hemorrhages in the offspring, oligohydramnios, and fetal nephrotoxicity.16,17 Additionally, a number of population-based cohort studies have found that NSAIDs are associated with an increased risk of spontaneous abortion, preterm birth, and low birth weight.25 NSAIDs in general appear to be safe during lactation when used for short durations.16,17

The short-term use of opiates appears to be safe in pregnancy. Because opiates’ sedative effects extend to the fetus, caution should be used when prescribed at term. Chronic use of opiates is discouraged in general because it may result in maternal as well as fetal addiction. Because opiates are poorly concentrated in milk, opiate analgesia may be used safely during breast-feeding.15

Antibiotics

First- through fourth-generation penicillins and their derivatives (including procaine, benzathine, clavulanate, sulbactam, and tazobactam) are considered safe for use in pregnancy, as is oral probenecid.16,17,26,27 Penicillins are considered safe during breast-feeding, but their use may interfere with culture results if a neonatal fever workup is required.15-17

First- through fourth-generation cephalosporins appear to be safe for use during pregnancy, although there are no controlled studies examining their safety.16,17,26-28 Some cephalosporins are excreted into breast milk and may have the same implications on the workup of neonatal sepsis as described for penicillin.15,17

Chloramphenicol is safe during pregnancy except at term. No relationship has been found between the use of chloramphenicol and congenital anomalies.16,17,27,29 Although it is considered safe throughout most of pregnancy, chloramphenicol should be used with caution at term. It has been associated with the development of cardiovascular collapse (the “gray baby” syndrome) in a neonate.16,17,26,27 The safety of chloramphenicol during breast-feeding is unknown; however, due to its potential toxicity, it is not recommended for use during lactation.15,17

The macrolides erythromycin, azithromycin, and clarithromycin are considered to be safe for use in pregnancy and compatible with breast-feeding, although there are no well-controlled studies examining their effects on the fetus.15-17 Some reports have linked erythromycin to pyloric stenosis, but these studies were not controlled.16,17,26,27 The estolate salt of erythromycin has also been associated with the development of hepatotoxicity in pregnant women and should be avoided during pregnancy.16,17,26,27 Clarithromycin has been associated with an increased risk of fetal and embryonic death as well as congenital malformations in animal species. To date, however, this has not been shown in humans. In addition, a prospective controlled multicenter study comparing the outcomes of pregnancies exposed to clarithromycin to matched controls did not find any differences in the types or patterns of malformations between the two groups.29,30 However, there appeared to be an increased number of spontaneous abortions in exposed women, which may have been due to confounding factors, and further studies are warranted. Azithromycin is poorly

concentrated in breast milk and may be the preferred agent in lactating mothers.15-17,27

Sulfonamides are safe for use in the second trimester and possibly safe in the first trimester, but they should be avoided at term. The primary use of sulfonamides in the emergency department is in the treatment of uncomplicated urinary tract infection, and in this circumstance, sulfamethoxazole is combined with trimethoprim. Trimethoprim is a folate antagonist and has traditionally been contraindicated in pregnancy because of an increased risk of neural tube defects. The sulfonamides readily cross the placenta to the fetus during all stages of gestation. Fetal levels may reach 90% of maternal plasma concentrations. Although sulfamethoxazole has been associated with an increase in congenital malformations in animals, most reports of sulfonamide exposure during pregnancy in humans have failed to demonstrate such an association.16,17 Sulfonamides are contraindicated in pregnancy near term because they theoretically compete with bilirubin for protein-binding sites, leaving large amounts of free bilirubin to diffuse, be deposited in the infant's brain, and cause kernicterus.16,17,31,32 To date, however, this complication has not been reported in neonates, presumably because free bilirubin is effectively cleared by the placental circulation. In contradistinction, kernicterus has occurred in newborns exposed to sulfonamides after birth.16,17 Sulfonamides are excreted into breast milk in low concentrations and are generally tolerated by a healthy neonate. They should be avoided, however, in ill or premature infants and in infants with hyperbilirubinemia or glucose-6-phosphate dehydrogenase deficiency.15

Aminoglycosides should be avoided during pregnancy. These drugs readily cross the placenta and their use in pregnancy has been linked to fetal ototoxicity and nephrotoxicity, especially when high doses are used.16,17 Gentamicin is secreted in small amounts in breast milk and is poorly absorbed from the gastrointestinal tract. It is compatible with lactation.15-17

Tetracycline should be avoided during pregnancy because it has been associated with the development of fatal fatty liver in pregnant women.16,17,26,27 It readily crosses the placenta and reaches the fetus, where it chelates calcium, causing abnormalities in bone growth and staining of decidual teeth. Tetracycline has also been associated with fetal genitourinary anomalies, inguinal hernias, and limb abnormalities.16,17,26,27

Doxycycline does not bind to calcium and is associated less with stained teeth than is tetracycline. Also, it does not appear to cause an increase in any type of congenital malformation. Despite these findings, doxycycline is not advocated for long-term use in pregnancy.16,17,26,27

Because tetracycline binds to breast milk calcium, only a small amount reaches the nursing infant, and it may be used for short periods (≤10 days) during breastfeeding.15-17 Because it does not bind to breast milk calcium, doxycycline is present in greater quantities in breast milk and is not recommended for use for prolonged periods.15-17,26,27

Fluoroquinolones have been linked to numerous toxic effects on bone and cartilage growth in animal models and have been discouraged from use during pregnancy, particularly during the first trimester.15-17,26,27 A 1998 prospective multicenter study, however, found no increase in premature birth, fetal distress, low birth weight (<2500 g), birth weight, or motor development when fluoroquinolones were used during pregnancy.13 The American Academy of Pediatrics (AAP) considers fluoroquinolones to be compatible with breast-feeding, because breast-fed infant plasma levels are low.15,27

Clindamycin has not been associated with birth defects in humans, and animal studies have failed to link clindamycin to congenital abnormalities in the offspring.16,17,26,27 The AAP considers clindamycin to be compatible with breast-feeding.15

Vancomycin has not been linked to birth defects in humans.16,17,26,27 Reports of auditory abnormalities and renal insufficiency in neonates of mothers treated with vancomycin are believed to be false positives.34 Vancomycin is excreted into milk but not well absorbed by the GI tract. Its effects on the nursing infant have not been studied.16,17

Linezolid has been linked to embryonic death, decreased weight, and abnormalities in cartilage and ossification in animal studies, but there is no information regarding its effects in humans. Its use in pregnant women should be limited to cases in which the maternal benefit will outweigh possible risk to the fetus.16,17

Nitrozofurantoin has not been linked to birth defects in animals or humans. However, there are rare reports of hemolytic anemia in the newborn when the drug is used near term, independent of glucose-6-phosphate dehydrogenase deficiency.16,17,35

Human data on the use of metronidazole during pregnancy are mixed.16,17,27 Because metronidazole is mutagenic and carcinogenic in mice, many physicians avoid prescribing it during pregnancy. An analysis of pooled data from case-control and cohort studies, however, did not reveal any increased incidence of congenital malformations even when metronidazole was used in the first trimester.36 It is therefore considered safe for use in the second and third trimesters, but because of its potential mutagenic effects it is not recommended for use in the first trimester.16,17,27 Furthermore, the AAP recommends using metronidazole with caution during lactation.15-17

G6PD, glucose-6-phosphate dehydrogenase; PEG-ELS, polyethylene glycol-electrolyte lavage solution.
**Antifungal Medications**

Nystatin has a long safety profile during pregnancy and lactation. It is poorly absorbed from skin, mucous membranes, and the GI tract, and it is considered the antifungal agent of first choice for treatment of mucocutaneous fungal infections. Clotrimazole, miconazole, and ketoconazole seem to be safe during pregnancy and lactation because they have not been associated with major birth defects. However, in a case-control study, a minor increase in the incidence of hypoplastic left ventricle was reported. In addition, ketoconazole is teratogenic in rats. For these reasons, clotrimazole, miconazole, and ketoconazole are considered second-line treatment of fungal infections in pregnancy. Fluconazole is teratogenic in high doses (>400 mg/day) and has been associated with an increased incidence of craniofacial and cardiovascular defects in offspring and multiple abnormalities of the skeleton and cartilage. These anomalies were not noted when lower doses were used or with single-dose (150 mg) therapy for vaginal candidiasis.

Ketocanazole, fluconazole, and itraconazole are excreted into breast milk. Based on the safe use of ketocanazole in neonates and the lack of negative reports, it is considered compatible with breast-feeding. 15-17

**Antituberculous Agents**

Untreated tuberculosis places the mother and fetus at greater risk than does the use of antituberculous medications. In addition, in a review of antituberculous treatment during pregnancy, no association was found between these medications and congenital malformations. Rifampin crosses the placenta and occasionally has been implicated in case reports of congenital anomalies and with hemorrhagic disease of the newborn. Because there are no controlled studies documenting these effects, rifampin continues to be recommended as first-line therapy along with isoniazid for treatment of pregnant women with tuberculosis. Ethambutol crosses the placenta but has not been associated with any congenital defects. All three antituberculous medications are considered compatible with breast-feeding. 15-17

**Antiviral Agents**

**Anticyclovir Drugs**

Acyclovir is a purine analogue commonly used in the treatment of herpesvirus infections. During pregnancy, acyclovir is indicated for life-threatening maternal herpes simplex virus infections, such as disseminated disease, herpes encephalitis, and varicella pneumonia, which carries a maternal mortality of 44% if untreated. The Centers for Disease Control and Prevention also recommends treatment of the first episode of genital herpes during pregnancy with oral acyclovir. There are no reports of teratogenicity or adverse effects in the fetuses or newborns of mothers using acyclovir or valacyclovir. Famciclovir was associated with congenital cardiovascular anomalies, hepatotoxicity, and death. Acyclovir is concentrated in milk, in which levels may be higher than in plasma. Because there are no reported adverse outcomes in infants of mothers taking acyclovir or infants treated with acyclovir for disseminated herpes, it is considered safe during breast-feeding. 15-17

**Anti-Influenza Drugs**

Amantadine appears teratogenic in some animals but not others. Its use in pregnant women is very limited, and one cannot draw any conclusions. Oseltamivir has no effect on embryonic or fetal development in animal studies. There appear to be no reports of its use in pregnancy, but based on its safety in animals, it may be used in human pregnancy, albeit cautiously. 16,17

**Anti-HIV Drugs**

Anti-HIV drugs may be indicated immediately after a needle-stick injury or sexual contact with an infected individual. No specific pattern of birth defects has been described with the use of these drugs, but there are a number of unanswered questions relating to the drugs’ mutagenesis and carcinogenesis and their long-term effects on the liver, heart, and reproductive system. 15,17

Animal and human data suggest that didanosine, lamivudine, stavudine, zidovudine, and zalcitabine present some risk, albeit small, of structural malformations and mitochondrial dysfunction in the developing fetus. However, even if a negative association is proven, the risk of morbidity and mortality from HIV infection far outweighs the risk of toxicity of most of these substances. Similarly, no specific pattern of birth defects has been described with protease inhibitors such as ritonavir and nelfinavir. When indicated, the benefits of treatment outweigh the drugs’ toxicities. 15-17

**Anticoagulants**

Warfarin (Coumadin) is a known human teratogen and affects 4 or 5% of exposed fetuses. The risk from exposure is greatest during 6 to 9 weeks of gestation and seems to be dose dependent. The fetal warfarin syndrome is associated with multiple abnormalities, such as hypoplasia of the nasal bones, midline dysplasia including agenesis of the corpus callosum, optic atrophy and blindness, mental retardation, seizures, and stippling of the bones with scoliosis and shortening of limbs. Because warfarin is so highly protein bound, only a little is secreted into milk, and use by breast-feeding mothers is acceptable. Caution should be used in breast-feeding premature infants because they may be at increased risk for intraventricular hemorrhage.

Unfractionated heparin is a highly charged heterogeneous molecule with a molecular weight between 5 and 35 kDa. It does not cross the placenta and does not present a direct risk to the fetus. Early reports on the use of heparin for the prevention or treatment of venous thromboembolism during pregnancy concluded that the risks to the fetus from premature, stillbirth, and hemorrhage might affect one third of infants. Recently, however, the increased risks previously associated with heparin were determined to be related to underlying maternal medical problems rather than heparin. When anticoagulation during pregnancy is required, heparin is considered the agent of choice. Its use is sometimes associated with maternal osteopenia and immune-mediated thrombocytopenia. Patients need careful monitoring for these adverse effects. The risk of maternal hemorrhage at delivery is significant. Because of its high molecular weight, heparin is not excreted in breast milk and is compatible with breast-feeding. 15-17

Low-molecular-weight heparin may be used during pregnancy and in the postnatal period for therapeutic or prophylactic anticoagulation. All currently available low-molecular-weight heparin products have been used safely.
Thrombolytic agents have been used successfully in pregnant women in cases of life-threatening pulmonary embolus or myocardial infarction. Experience with these agents during pregnancy, however, remains limited. To date, no teratogenic effects have been reported in humans, but maternal hemorrhage occurred when alteplase was used during the intrapartum period. Most thrombolytics are thought to be compatible with breast-feeding because of their short half-life.

**Special Populations**

**The Pregnant Patient**

*Phenobarbital is considered a class D medication in pregnancy.* 16,17

Adenosine is a naturally occurring compound that is metabolized quickly in the body. It has been used safely throughout pregnancy and is the drug of choice for terminating maternal supraventricular tachycardia, 32 despite the absence of large-scale studies. 6 Adenosine has also been used safely in terminating incessant tachycardia in the fetus. 31 Adenosine is likely safe in lactation. 16,17

Amiodarone, a class D agent, is not recommended in pregnancy, except in refractory cases of supraventricular and ventricular tachycardias of the mother or the fetus. 14,35 It contains large amounts of iodine and has been associated with congenital goiter and transient neonatal hyperthyroidism and hypothyroidism. 16,17,36,37 In addition, amiodarone use during pregnancy has been linked to many congenital abnormalities, including growth retardation, structural cardiac abnormalities, corneal deposits, and developmental delay. 16,17,54 Because of its high iodine content, its excretion into milk, and its long elimination half-life, amiodarone should not be used in nursing mothers. 16,17

Digoxin, disopyramide, and quinidine are all considered safe for use during pregnancy and lactation. 16,17 None have been linked to congenital defects in humans or animals. Of the three agents, digoxin and quinidine have the longest safety records in pregnancy and are first-line agents for the treatment of significant maternal dysrhythmias. 16,17 They have also been successfully used in fetal tachycardia. 58,59 However, maternal overdoses of digoxin resulting in fetal death have occurred. 60 Although considered safe during pregnancy, disopyramide has been associated with premature uterine contractions and labor. 61

Lidocaine is a weak base. It rapidly crosses the placenta and becomes ion trapped in the fetus. There is no evidence of a
Procainamide is also well tolerated and should be considered a first-line treatment of wide-complex tachydysrhythmias during pregnancy.55,58 The use of procainamide in nursing mothers is controversial because it and its metabolite, N-acetyl procainamide, have been found in breast milk.15,17

Encainide and flecainide are newer class IC antiarrhythmic agents that are structurally related to procainamide. Both have been used safely to terminate maternal and fetal tachycardia.16,17 A few negative fetal effects have been noted with the use of flecainide, including hyperbilirubinemia, hepatotoxicity, and loss of fetal heart rate variability.62,63 Both encainide and flecainide are found in breast milk. Although experience with encainide is limited, the AAP considers flecainide compatible with breast-feeding.16,17

Ibutilide is a class III antiarrhythmic used to terminate atrial fibrillation and flutter. Although there are no reports of its use in pregnancy in humans, when used in high doses, ibutilide was found to be teratogenic in rats.16,17 Ibutilide may be used in refractory cases in which the benefits of therapy outweigh any fetal risk.16,17

Sotalol does not appear to have teratogenic effects in animals.16,17 It has been used in pregnant women to treat hypertension. In these cases, bradycardia in the newborn was noted, which persisted for 24 hours. Sotalol has also been used successfully to terminate in utero fetal supraventricular tachycardia.16,17

Isoproterenol is indicated for refractory high-grade atrioventricular block and for torsades de pointes associated with prolonged QT interval. Data from animal studies have not shown any association between isoproterenol and developmental toxicity. It is also considered compatible with breast-feeding.16,17

Vasopressors

Dobutamine is an inotrope used in the setting of cardiac dysfunction and sepsis. Data from animal studies have not revealed any untoward reproductive effects. Effects in humans are not known, but one case report did not reveal any effects on the fetus.16,17,63

Dopamine and other vasopressors offer a maternal benefit that far outweighs the possible deleterious effects on the fetus and should not be withheld if indicated. Dopamine has been associated with increased uterine vascular resistance in animal studies, but no significant fetal side effects directly related to the drug have been reported. In addition to its use in maternal shock, dopamine has been successfully used in low doses to improve cardiac and urine output in patients with preeclampsia and oliguria.69

Epinephrine has been used to treat shock from any cause during pregnancy. However, it has been associated with anoxic injury to the fetus, intracranial hemorrhage, and an increased incidence of inguinal hernias.16,17,67 Safety during breast-feeding has not been studied.

Norepinephrine is associated with an increased incidence of cerebral hemorrhage, skeletal abnormalities, and a significant decrease in placental blood flow and fetal oxygenation in animal studies.16,17,68 Its safety during breast-feeding has not been studied.

Antihypertensives

Hypertension complicates 12% of pregnancies and accounts for 18% of maternal deaths in the United States.69 Previously, the most commonly used drug in hypertensive emergencies was hydralazine, but other medications currently available, such as labetolol and nifedipine, appear to be as effective and possibly safer than hydralazine.

Angiotensin-converting enzyme (ACE) inhibitors are classified as category D drugs and are contraindicated for use during pregnancy. ACE inhibitors are embryocidal in animals and increase the rate of stillbirths in some species. Although they seem to be safe in humans during the first trimester of pregnancy, many adverse fetal effects have been noted with their use during the second and third trimesters, precluding their use.16,17,37,70 Reported adverse neonatal effects include oligohydramnios, anuria, renal agenesis resulting in death, increased risk of stillbirth, intratneurose growth retardation (IUGR), fetal skull abnormalities, pulmonary hypoplasia, respiratory distress syndrome, and fetal and neonatal hypotension. Captopril and enalapril are considered compatible with breast-feeding.15,17

Angiotensin II receptor antagonists should be avoided during pregnancy because their use has been reported to result in fetal abnormalities similar to the abnormalities seen with ACE inhibitors, including renal agenesis, neonatal anuria, oligohydramnios, IUGR, persistent patent ductus arteriosus, abnormal ossification, and death.16,17 Their safety in lactation is unknown.

Beta-blockers have become a first-line treatment for hypertension in pregnancy.71,72 All beta-adrenergic blocking agents cross the placenta. The most experience with beta-blockers has been with women requiring treatment during the last trimester of pregnancy, at which time they seem to be safe. Long-term in utero exposure and first-trimester exposure have not been studied.16,17,37 Labetalol is the antihypertensive of choice during pregnancy.71,72 It has not been associated with any teratogenic effects in animal studies. Human reports of its use in the treatment of hypertension during pregnancy have not revealed any significant effect on the fetal birth weight or fetal heart rate.16,17,37 Transient neonatal hypotension and bradycardia may be observed when used at term. However, compared with traditional therapies for pregnancy-induced hypertension, labetolol appeared to reduce the blood pressure more smoothly than either hydralazine or diazoxide.16,17,71,73 Furthermore, it was associated with fewer cesarean sections than either of the two drugs.73 Atenolol and metoprolol are considered safe in pregnancy but only when used for short periods of time.16,17,73 There are reports of fetal harm when atenolol is used in the first trimester. Atenolol has also been associated with IUGR when used for prolonged periods during pregnancy, and when given near term, it is associated with persistent beta blockade in the newborn.16,17,73 Similarly, propranolol is associated with fetal and neonatal adverse effects, especially when doses exceeding 160 mg/day are used. These adverse effects include IUGR, hypoglycemia, bradycardia, respiratory depression at birth, and hyperbilirubinemia. Esmolol has also been associated with fetal bradycardia, neonatal bradycardia, and hypotonia as well as fetal distress requiring emergent cesarean section.74 It should therefore be used only if the benefits to the mother outweigh the risks to the fetus and if other options have failed. Beta-blockers are reportedly safe in breast-feeding, but close monitoring of the infant for adverse effects is recommended.15,17

Calcium channel blockers are indicated in the treatment of hypertension and a number of supraventricular rhythm disturbances during pregnancy.16,17,71 Nifedipine and cardizem have also been used as tocolytic agents. In addition, verapamil has been used to terminate maternal as well as fetal tachycardia.75 Despite negative reproductive studies in animals, the calcium channel blockers are used extensively during the second and
third trimesters in humans and are considered safe for use during these stages of pregnancy.\textsuperscript{16,17,37,76} Whereas cardizem appears to be safe at all stages of pregnancy, nifedipine was associated with fetal distress secondary to maternal hypotension when it was used sublingually.\textsuperscript{16,17} In addition, when used in conjunction with magnesium, nifedipine appeared to potentiate the neuromuscular blocking effects of magnesium, resulting in profound muscle weakness, difficulty in swallowing, and paradoxical respirations.\textsuperscript{77} Calcium channel blockers are considered safe for use during breast-feeding.\textsuperscript{15,17}

Thiazide diuretics have been used successfully for the treatment of hypertension in pregnancy but may result in electrolyte abnormalities in neonates when given near term.\textsuperscript{16,17,71} An increase in perinatal mortality and congenital defects possibly caused by volume depletion has been reported.\textsuperscript{16,17} First-trimester use has been associated with an increase in congenital abnormalities.\textsuperscript{16,17} Diuretics are not recommended for the treatment of pregnancy-induced hypertension because of the maternal hypovolemia characteristic of this disease. Other risks to the pregnancy include higher rates of uterine inertia and meconium staining.\textsuperscript{78} In the neonate, there is a higher incidence of hypoglycemia, thrombocytopenia, hyponatremia, hypokalemia, and death from maternal complications.\textsuperscript{16,17}

Moreover, thiazide diuretics may have a direct effect on smooth muscle and inhibit labor. Bendroflumethiazide, chlorothalidone, and hydrochlorothiazide are considered safe during breast-feeding.\textsuperscript{16,17} Loop diuretics are generally not used in pregnancy unless indicated for congestive heart failure. They have not been found to cause major adverse outcomes in the fetus.

Hydralazine is safe in pregnancy. It was previously considered the drug of choice for the parenteral treatment of acute severe hypertension during pregnancy.\textsuperscript{71} However, it has been associated with higher rates of maternal hypertension compared to labetolol, which may affect perinatal outcome.\textsuperscript{16,17,37,71} It is also associated with a lupus-like syndrome, which has been reported in both mother and neonate.\textsuperscript{16,17,37,79} Because other agents, particularly labetolol, are safer and just as effective, hydralazine is no longer recommended as a first-line agent in the treatment of hypertensive emergencies in pregnant women.\textsuperscript{71} Hydralazine is safe in lactation.\textsuperscript{16,17,79}

Methyldopa is considered safe in pregnancy, and most reviews have not linked it to any adverse effects on the pregnancy.\textsuperscript{16,17} Many clinicians still use it as first-line therapy to treat hypertension during pregnancy. Methyldopa is compatible with breast-feeding.\textsuperscript{31}

Clonidine has been safely used throughout pregnancy, but experience during the first trimester is very limited.\textsuperscript{80} A few insignificant adverse fetal effects attributable to clonidine have been reported. Transient neonatal hypertension has been reported in neonates with in utero exposure to clonidine.\textsuperscript{16,17,37,80} Its effects on breast-feeding neonates are unknown, but it is considered to be compatible with breast-feeding.\textsuperscript{15,17}

Nitroglycerin has not been shown to cause fetal harm in animal studies. Limited reports in humans do not show any major effects on the fetus or neonate. Nitroglycerin is rarely used during pregnancy, but it appears to be safe, effective, rapidly acting and short-acting agent.\textsuperscript{16,17,81,89} It appears to be effective in relieving intrapartum fetal distress related to uterine hyperactivity.\textsuperscript{51}

Nitroprusside is used for the treatment of hypertensive emergencies in pregnancy has the same advantages and disadvantages seen in nonpregnant patients.\textsuperscript{16,17,71} Advantages include its rapid onset, rapid metabolism, and rapid excretion. Disadvantages of nitroprusside include the need for constant monitoring and cumbersome administration. During prolonged administration of high doses, nitroprusside may result in cyanide toxicity. It readily crosses the placenta, and fetal levels of cyanide can increase as high as twice maternal levels. Standard doses do not seem to subject the fetus to major risk of toxicity, but with the availability of safer alternatives, notably labetalol, nitroprusside is considered a second-line agent.\textsuperscript{16,17,37} When used, it is recommended to monitor plasma and red blood cell cyanide and maternal pH. Nitroprusside is considered a category C medication. No data are available on its use during breast-feeding.

**Asthma, Allergy, and Upper Respiratory Infection Medications**

Pregnant women with asthma are at risk of neonatal death, preterm birth, low-birth-weight infants, preeclampsia, and small-for-gestational-age infants.\textsuperscript{71,82} Asthmatic mothers may also have a higher rate of chorioamnionitis, hypertensive disorders of pregnancy, cesarean section, and prolonged hospital stay compared to control mothers.\textsuperscript{82,83} Better asthma control has been associated with an improved outcome.\textsuperscript{71}

The beta-adrenergic medications albuterol, metaproterenol, and terbutaline are safe for use in pregnancy. None have been linked to congenital anomalies.\textsuperscript{16,17} Beta-adrenergic agents have also been used during the last trimester to treat prema- ture labor. Adverse reactions are related to the drugs’ cardiovascular and metabolic effects, which are transient and generally well tolerated by the fetus.\textsuperscript{16,17,83,84} Transient hyperglycemia followed by insulin secretion may also occur, resulting in neonatal hypoglycemia, especially in diabetic patients.\textsuperscript{16,17} Long-term use of albuterol has not been associated with adverse effects. Albuterol is compatible with breast-feeding.\textsuperscript{15,17} Long-acting beta-agonists also appear to be safe during pregnancy.\textsuperscript{16,17,83}

Ipratropium has not been found to be teratogenic in numerous animal models. Although there are few human data, ipratropium seems to be safe for use during pregnancy and lactation.\textsuperscript{15-17}

Cromolyn sodium is safe in pregnancy. Cromolyn has not been associated with any significant risk of birth defects or negative perinatal outcomes.\textsuperscript{16,17,82,83}

Corticosteroids are commonly used during pregnancy for the treatment of various disorders, including autoimmune diseases, hyperemesis gravidarum, and asthma. Inhaled corticosteroids are the main therapy for the prevention of asthma exacerbations during pregnancy. Oral corticosteroids are the mainstay of therapy for acute exacerbations of asthma. Although they are not considered human teratogens, there may be a slightly increased incidence of orofacial clefts when oral steroids are used during the first trimester.\textsuperscript{16,17,37,85} Furthermore, their use in the third trimester has been linked to an increased incidence of preterm delivery, low birth weight, preeclampsia, and cataracts in the newborn.\textsuperscript{16,17,37,85} Other authors have also raised concerns about the development of congenital adrenal hyperplasia in newborns.\textsuperscript{16,17} Prednisolone is considered safe during breast-feeding.\textsuperscript{15,17}

Data on the use of leukotriene antagonists in pregnancy are limited. One study did not find an association with congenital abnormalities, but there was a slight increase in intrauterine growth restriction. However, these results should be interpreted with caution because of the small sample size of the study.\textsuperscript{86} Zileuton is mutagenic in animal studies and should be avoided during pregnancy and lactation.\textsuperscript{16,17}

Antihistamines have been safely used in the treatment of allergic reactions during pregnancy and as antiemetics in the treatment of nausea and vomiting during pregnancy. Antihis-
tamines have been linked to the development of retrolental fibroplasia (retinopathy of prematurity) in premature infants when given during the last 2 weeks of pregnancy. A meta-analysis that reviewed 24 studies involving more than 200,000 patients confirmed the safety of antihistamines, including chlorpheniramine, diphenhydramine, doxylamine, hydroxyzine, and meclizine, during pregnancy. The newer generation antihistamines, such as cetirizine and loratadine, also appear safe during pregnancy. They may be acceptable alternatives for severe allergies if the first-generation antihistamines are not tolerated. First-generation antihistamines are not recommended during breast-feeding because they may inhibit lactation. In addition, neonates receiving antihistamines appear to develop serious adverse CNS effects, including seizures, especially when premature.

Decongestants are not recommended during pregnancy. Decongestants with strong vasoconstrictive properties, such as phenylephrine and pseudoephedrine, cause placental vasoconstriction, resulting in an increased incidence of abnormalities typically associated with placental vascular disruption, such as gastrochisis and intestinal atresia.

Gastrointestinal Medications

Phenothiazines, such as promethazine, chlorpromazine, perphenazine, and metoclopramide, are dopamine antagonists commonly used in the treatment of nausea and vomiting during pregnancy, and they have not been linked to congenital abnormalities. Caution should be used with chlorpromazine because it may cause hypotension and also with promethazine at term because it may cause respiratory depression.

Ondansetron, a serotonin 5-HT3 receptor antagonist, has not been linked to any fetal malformations, but it may not offer any additional antiemetic activity compared to the phenothiazines. Newer 5-HT antagonists, such as dolasetron and granisetron, also appear to be safe during pregnancy, although experience is limited. These agents are most likely compatible with breast-feeding.

The H2 receptor antagonists ranitidine, famotidine, and cimetidine have not been linked to any congenital malformations and appear to be safe for long-term use during pregnancy and lactation. However, one report has linked the use of antacids during pregnancy to an increased incidence of asthma during childhood.

Diabetes Medications

Insulin has been used safely during pregnancy and lactation for many years and is the drug of choice for glucose control in pregnancy. Sulfonylurea drugs have traditionally been not used during pregnancy. They are regarded as possibly teratogenic and less effective than insulin in the control of gestational diabetes. Sulfonylurea drugs have also been associated with neonatal hypoglycemia when used at term. In reality, there is little information about their use during pregnancy, and in a randomized study, glyburide proved to be as effective and safe during pregnancy as insulin. Glyburide and glipizide are highly protein bound and are not likely to pass into breast milk; nursing infants should be monitored.

Metformin has not been associated with fetal malformations in animals, and there are no controlled studies analyzing its effect in humans. Metformin has been associated with serious adverse effects in adults, including severe life-threatening metabolic acidosis and hepatotoxicity. Because of its potential for serious effects in adults, metformin is not recommended for use in lactating mothers.

Anesthetics and Sedatives

The short-term use of benzodiazepines during pregnancy appears to be safe. However, the safety of benzodiazepines during pregnancy has been debated because data on the fetal effects of these drugs have been inconsistent. Some case reports have linked their use during the first trimester of pregnancy to increased risk of oral clefts, but in a meta-analysis of pooled data from the cohort studies, no association was found between fetal exposure to benzodiazepines and the risk of oral clefts. Different benzodiazepines also have been linked to different effects and risks. Lorazepam, for example, has been linked to anal atresia; clonazepam has been associated with congenital cardiac abnormalities; and oxazepam and diazepam have been linked to specific dysmorphic features, CNS abnormalities, and growth defects. Midazolam, on the other hand, has not been linked to any developmental abnormalities. Neonates exposed to benzodiazepines may exhibit signs of toxicity, including apnea, cyanosis, unresponsiveness, hypotonia, poor feeding, and withdrawal symptoms characterized by irritability and tremulousness. Because of the reported risk of apnea, it is recommended that neonates exposed to benzodiazepines through breast-feeding be monitored closely.

Ketamine is a rapidly acting dissociative anesthetic that is commonly used in pediatric procedural sedation and may be used in rapid sequence intubation (RSI). It has not been associated with any developmental malformations. Ketamine has a dose-related oxytocic effect, and in high doses it has been associated with uterine tetany, increases in maternal blood pressure and heart rate, and increased neonatal muscle tone. Neonatal depression has also been reported. Ketamine may remain in breast milk for 12 hours.

Propofol is a rapidly acting sedative anesthetic that rapidly crosses the placenta. It has not been linked to any congenital defects when used in pregnancy. When high doses are used at term, it can cause neonatal respiratory and CNS depression. Propofol is excreted in breast milk in negligible amounts.

Thiopental is an ultra-short-acting barbiturate that may be used during RSI or for persistent status epilepticus. Thiopental appears to be safe during pregnancy, but a slight reduction in birth weight has been noted when high doses are used. Etomidate is an ultra-short-acting hypnotic agent that is commonly used for procedural sedation or RSI. No reports on developmental effects of etomidate have been published. However, newborns of mothers undergoing cesarean section with etomidate were found to have significant reductions in serum cortisol concentrations 1 hour after delivery. Thiopental and etomidate appear to be safe during pregnancy, but a slight reduction in birth weight has been noted when high doses are used.
studied; however, it is probably safe because it is hydrolyzed quickly.16,17,96

Rocuronium and vecuronium are nondepolarizing neuromuscular blocking agents used in RSI. The effects of neuromuscular blocking agents on organogenesis are not known, but these agents are not thought to pose a significant teratogenic risk.16,17,94 Because of their chemical properties, very little of either drug crosses the placenta, and very little is excreted in milk.16,17,94 Their effects on lactation are unknown but probably would be minimal.16,17

Antidotes

N-acetylcysteine has been used successfully and without untoward effects in pregnant women who have overdosed on acetaminophen.18,19 No teratogenic effects have been reported.

Deferoxamine is indicated for iron toxicity occurring from iron overdose or from multiple transfusions in thalassemia patients. It has been associated with developmental effects on ossification in some animal species.16,17 Experience in humans is limited, but it does not appear to affect the fetus.99 The effects of deferoxamine on the nursing infant are not known.

Dimercaprol or British antilewisite is a metal chelating agent that is used as an antidote for acute mercury, lead, arsenic, and gold poisoning. It has also been used in Wilson’s disease. It is teratogenic in mice and has been associated with increased mortality, growth retardation, cleft facial features, cerebral herniation, and abnormal digits, but experience in humans is limited.16,17,97 In certain cases of heavy metal poisoning, the maternal benefits of dimercaprol use outweigh its potential risks to the unborn fetus. Breast-feeding is not recommended for patients poisoned by heavy metals.

Flumazenil is a benzodiazepine antagonist. No teratogenic effects have been reported in animals, and data on humans are very limited.16,17 Its use in pregnancy depends on the potential maternal benefit compared to possible risks to the fetus.

Fomepazole is a competitive inhibitor of alcohol dehydrogenase indicated in cases of methanol and ethylene glycol poisoning. Its use during pregnancy has not been studied in animals or humans. Its safety during pregnancy is not known.16,17 In cases of toxic alcohol poisoning, the benefits of fomepazole use outweigh its potential risks to the newborn. Breast-feeding is not recommended for patients poisoned by alcohol.

Activated charcoal is not absorbed and is probably safe for use in pregnancy and lactation, although there are no published studies regarding the effects of charcoal use during pregnancy.16,17

Digoxin fragment (DIG Fab) therapy is indicated for life-threatening digoxin overdose and is being studied for treatment of preeclampsia. There are very few case reports of the use of DIG Fab immune globulin during pregnancy. A conclusion on the effects of DIG Fab cannot be made based on these reports. However, in cases of life-threatening digitalis overdose with arrhythmias, the benefits of treatment of the mother may outweigh the risk to the fetus. DIG Fab is not likely to be excreted in large amounts in milk, and it is probably safe for use during lactation.16,17

Hydroxyocobalamin is a vitamin that is indicated in the treatment of cyanide toxicity. Studies in animals do not reveal an association with any developmental abnormality.16,17

Methylene blue is used in the treatment of methemoglobinemia. In the past, it was injected into the amniotic sac to identify twins and to detect rupture of the membranes, but these practices were associated with hemolytic disease in the newborn, hyperbilirubinemia, and deep blue staining of the newborn.16,17,98 Methylene blue in pregnancy has also been associated with an increased incidence of intestinal obstruction and atresia in the newborn.99 The effects on nursing infants are unknown but probably minimal.16,17

Naloxone, used to reverse the effects of opiates in an overdose, readily crosses the placenta. Naloxone has not been associated with reproductive abnormalities; however, its use in opiate-addicted mothers may precipitate withdrawal in both mother and term fetus.16,17 It is compatible with breast-feeding.15

Phyostigmine is an anticholinesterase agent indicated in cases of severe anticholinergic poisoning associated with delirium. Experience with the medication during pregnancy is limited, and its effects on the developing fetus are unknown.16,17 Use of phyostigmine at term was associated with only mild decreases of Apgar scores at 1 and 5 minutes.100 Polyethylene glycol (PEG) is not absorbed systemically. It is probably safe for use in pregnancy and lactation, although there are no reports on the effects of PEG in pregnancy.16,17

Pralidoxime is indicated for organophosphate/cholinergic poisoning because it is able to reactivate cholinesterase. Experience with pralidoxime in pregnancy is limited, and its effects on fetal development are not known.16,17 In cases of organophosphate poisoning, the benefits to the mother generally outweigh the possible risk to the fetus.

Pyridoxine is a vitamin required for good maternal health and good fetal development. It is indicated in isoniazid poisoning and in gyromitrin mushroom poisoning. Its use has been advocated in some for nausea and vomiting of pregnancy and gestational hypertension and diabetes. It has not been associated with any adverse developmental effects, and it is safe in lactation.16,17

Saccharin is a lead chelator that is indicated in lead poisoning. It has been linked to congenital defects in animal models, possibly due to effects on zinc and copper metabolism.16,17 Experience with the use of saccharin in pregnancy is limited to case reports of women poisoned with lead. No conclusions can be drawn on its teratogenic effects.101

KEY CONCEPTS

- Chemically induced birth defects are believed to be responsible for approximately 1 to 3% of anomalous births.
- The age of the fetus is crucial in determining the impact of any given exposure; during the time of organogenesis (days 21–56 of fetal life) when major body organs are formed, exposure to a teratogen may result in major anatomic defects.
- Certain medications, such as anticonvulsants, warfarin derivatives, NSAIDs, sulfonamides, fluoroquinolones, ACE inhibitors, and oral hypoglycemic agents, are known teratogens or cause potential toxic effects in the newborn and should be avoided, if possible, during pregnancy.
Emergency department (ED) births are rare. In most cases, the emergency physician will identify patients in labor and triage them to the obstetric service for urgent management, maintaining a continuum of care with their primary providers. Because some births are precipitous and obstetric resources may not be immediately available, the emergency physician must possess the basic skills for intrapartum management of both normal and abnormal deliveries. In addition, a general knowledge of postpartum care is required in case of the occasional out-of-hospital delivery.

Limitations of the Emergency Department

The ED is a suboptimal location for the management of a complicated delivery. The obstetric suite has experienced personnel and better resources, including tocodynamometry, fetal scalp electrodes, intruterine pressure monitors, vacuum extractors, and forceps. Also, the obstetrician usually has prenatal care information for each patient that helps to optimize maternal and fetal outcomes. Such information includes accurate gestational dates, the presence of multiple gestations, estimated fetal weights, detailed maternal pelvimetry, placental anatomy, amniocentesis results, maternal blood type and Rh factor, and prior documented obstetric complications. This information allows the obstetrician to anticipate complications of labor and delivery. It is difficult, if not impossible, to obtain these data in the ED while preparing for imminent delivery.

Epidemiology of Emergency Delivery

In 2004, the perinatal mortality rate in the United States was 6.2 per 1000 live births and fetal deaths (>20 weeks of gestation). Extensive epidemiologic data regarding the subgroup of ED deliveries are lacking. However, it has been established that delivery complications and mortalities do occur with greater frequency in the ED. In fact, the perinatal mortality rate for ED deliveries has been approximated at 8 to 10%.

There are multiple causes of the “high-risk” ED delivery profile. The ED is often selected by an obstetric population with unexpected complications. Antepartum hemorrhage, premature rupture of membranes (PROM), eclampsia, premature labor, abruptio placentae, precipitous delivery, malpresentation, and umbilical cord emergencies are overrepresented in the ED population.

Psychosocial factors further skew the epidemiology of ED deliveries. Women who present with precipitous deliveries often have had very little or no prenatal care. Pregnant women who have drug or alcohol problems or are victims of domestic violence represent a disproportionate number of patients who deliver in the ED. Women who are unaware or in denial of their pregnancies, or immigrants without access to other medical care, also present to the ED when labor begins. For each of these groups, all of which are compromised by psychosocial factors, inadequate prenatal care makes the subsequent delivery high risk.

Patient Transfer Considerations

Because of the high risk associated with ED delivery, patients should be transported to a facility that has obstetric and neonatal resources as appropriate. The management of a premature infant may require highly specialized intensive care that is unavailable at many community hospitals. The desire to transfer a woman with an impending high-risk delivery to such a facility must be tempered, however, by clinical and medicolegal judgment.

Medicolegal Considerations

Transfer, with resultant en route delivery, can be disastrous for the mother and fetus. Such a transfer also violates federal law. The Consolidated Omnibus Reconciliation Budget Act (COBRA) of 1989 was based on an “inappropriate” obstetric transfer. Federal law has identified labor as a condition unsuitable for transfer because of its unstable nature. Although the intent of this legislation is to protect women from medical and financial “dumping,” COBRA also may force emergency physicians to perform difficult high-risk deliveries that might have better outcomes if transferred.

Nursery Requirements

For many ED deliveries, labor will have progressed to a point where tocolysis is contraindicated and delivery is imminent. Generally, this is the point when the mother feels the urge to push or the head is crowning. Whenever possible, a neonatologist or pediatrician should attend high-risk preterm (<36 weeks’ gestation) deliveries, and preparations for neonatal
resuscitation and high-level nursery care should be initiated (Box 179-1).

**NORMAL DELIVERY**

Although the epidemiology and high complication rate associated with ED births demand caution, most are normal deliveries. Knowledge of normal labor and delivery mechanics aids safe vaginal delivery and facilitates the identification of complications.

Whenever a woman in the third trimester of pregnancy seeks treatment in the ED, the possibility that she is in labor must be considered. A wide array of nonspecific symptoms may herald the onset of labor. Abdominal pain, back pain, cramping, nausea, vomiting, urinary urgency, stress incontinence, and anxiety can all be symptoms of labor. After 24 weeks’ gestation, any medical assessment should include the mother and the fetus because fetal viability becomes established near that time. In addition, given the generally high-risk nature of this patient population and the abundance of bodily fluids that the health care provider and newborn are exposed to during delivery, serologic testing for infectious disease may be warranted. With the development of rapid bedside testing technology, human immunodeficiency virus (HIV) and hepatitis screening before delivery is indicated in a significant percentage of high-risk pregnancies cared for in such centers.

**Stages of Labor**

**First Stage of Labor**

The first stage of labor is the cervical stage, ending with a completely dilated, fully effaced cervix. It is divided into a latent phase, with slow cervical dilation, and an active phase, with more rapid dilation. The active phase begins once the cervix is dilated 3 cm. In multiparous women, the active phase can progress rapidly into stage 2 of labor (delivery of the fetus). Most women who deliver in the ED arrive while in the active phase of stage 1 or in early stage 2 labor (Fig. 179-1).

The duration of the first stage of labor averages 8 hours in nulliparous women and 5 hours in multiparous women. During this time, frequent assessment of fetal well-being is important. For low-risk pregnancies, fetal heart tones should be auscultated approximately every 15 minutes. For higher risk pregnancies, continuous external electrical monitoring may help identify fetal distress, allowing appropriate intervention.

Abdominal examination using Leopold’s maneuvers may confirm the lie of the fetus (Fig. 179-2). After labor has begun, particularly during the active phase of stage 1, Leopold’s maneuvers are difficult to use. The firm contractions of the uterus prevent the identification of fetal “small parts.” Other modalities of assessing the lie, such as ultrasonography, may be necessary if presentation remains in question.

Maternal examination also provides a rough guide to gestational age. At 20 weeks’ gestation, the uterine fundus reaches the umbilicus. Approximately 1 cm of fundal height is added per week of gestation until 36 weeks. At that time, the fundal height decreases as the fetus “drops” into the pelvis (Fig. 179-3). These estimates help to establish gestational age rapidly.

---

**Distinguishing False from True Labor**

Braxton Hicks contractions, or false labor, must be differentiated from true labor. During the third trimester, the uterus develops into a contractile organ. After 30 weeks of gestation, the previously small and uncoordinated contractions of the uterus become more synchronous and may be perceived by the mother. Braxton Hicks contractions do not escalate in frequency or duration, in contrast to the contractions of true labor. By definition, this muscular activity is associated with minimal or no cervical dilation or effacement. Examination should also reveal intact membranes. Care not to rupture the membranes is important to avoid inducing labor prematurely. If the diagnosis remains in doubt, external electrical monitoring of uterine activity can be utilized to rule out true labor. Any discomfort associated with false labor is usually relieved with mild analgesia, ambulation, or change in activity.

Unlike false labor, true labor is characterized by cyclic uterine contractions of increasing frequency, duration, and strength, culminating in delivery of the fetus and placenta. In contrast to Braxton Hicks contractions, true labor causes cervical dilation to begin, marking the first stage of labor.

**Bloody Show**

Early in pregnancy, the cervix becomes increasingly vascular and develops edema, giving the cervix a boggy texture. The vascularity of the cervix also increases, giving rise to Chadwick’s sign (a blue-violet coloration). At the onset of labor, the cervical mucus plug is expelled, resulting in what is called a bloody show. The bleeding associated with the process is slight, and usually only a few dark red spots are noticed. The dark color is due to its venous origin, and it is admixed with the mucous components of the cervical plug. The significance of a bloody show is that it is a fairly reliable indicator of the onset of true labor, specifically stage 1. Bloody show is not a contraindication to vaginal examination for determination of cervical effacement and dilation. If bleeding continues or is of a larger volume, more serious causes should be suspected, such as placenta previa and placental abruption, which are contraindications for a vaginal examination.
Figure 179-1. Stages of labor and delivery. Stage 1, cervical stage; stage 2, fetal expulsion; stage 3, placental expulsion (20 minutes); stage 4, uterine contraction (1 hour postpartum).

The accurate determination of the stage of labor depends on examination of the cervix. A sterile approach using sterile gloves, a sterile speculum, and povidone-iodine (Betadine) solution is indicated to prevent ascending infection, such as chorioamnionitis. On pelvic examination, the clinician should determine the following:

1. **Effacement** refers to the thickness of the cervix. A paper-thin cervix is 100% effaced.
2. **Dilation** indicates the diameter of the cervical opening in centimeters. Complete, or maximum, dilation is 10 cm.
3. **Position** describes the relationship of the fetal presenting part to the birth canal. The most common position of the head is occiput anterior.
4. **Station** indicates the relationship of the presenting fetal part to the maternal ischial spines (Fig. 179-4).
5. **Presentation** specifies the anatomic part of the fetus leading through the birth canal.

In 95% of all labors, the presenting part is the occiput, or vertex. On digital exam, a smooth surface with 360 degrees of firm bony contours and palpable suture lines is noted. Palpation of the suture lines and the fontanels where they join allows the examiner to determine in which direction the fetus is facing. Three sutures radiate from the posterior fontanel, and four radiate from the anterior fontanel (Fig. 179-5). The lateral margins should be examined carefully for fingers or facial parts that indicate compound or brow presentations.

When the clinician suspects rupture of membranes, a sterile speculum examination should be performed. This may reveal pooling of amniotic fluid. Two tests used to confirm the presence of amniotic fluid include a fernlike pattern when the fluid is allowed to dry on a microscope slide and the use of nitrazine paper, which should turn blue, indicating an alkaline amniotic fluid (pH > 6). Although vaginal blood, cervical mucus, semen, and infection can interfere with results, sensitivities of both nitrazine paper and ferning in detecting amniotic fluid are nearly 90%.

Of note, if vaginal bleeding is evident, both digital and speculum examination of the pelvis should be deferred until ultrasound can be obtained to rule out placenta previa.

**Second Stage of Labor**

The second stage of labor is characterized by a fully dilated cervix and accompanied by the urge to bear down and push with each uterine contraction. The fetal station is advanced to +3, with crowning of the presenting part as expulsion begins. Stage 2 uterine contractions may last 1 or 2 minutes and recur after a resting phase of less than 1 minute. The median duration of this stage is 50 minutes in nulliparous women and 20
minutes in multiparous women. More rapid progression through stage 2 should be anticipated for low-birth-weight premature infants. A prolonged second stage of labor is defined as more than 3 hours in nulliparous women if regional anesthesia is administered, more than 2 hours in nulliparous women without anesthesia or multiparous women with regional anesthesia, and more than 1 hour in multiparous women without regional anesthesia.20 Prolonged second stage of labor is associated with an increase in maternal complications, including postpartum hemorrhage, infection, and severe vaginal lacerations.21

**Antenatal Fetal Assessment.** The assessment of any woman in the third trimester includes an assessment of fetal well-being. After 24 weeks’ gestation, the fetal condition should affect clinical decision-making. During labor and delivery, the identification of fetal distress and appropriate intervention can reduce fetal morbidity and mortality.

There are currently three methods of assessing a fetus in utero. Clinical monitoring, electrical monitoring, and ultrasonography all have a role in the assessment of the fetus.22,23 External electrical monitoring and ultrasonography merit consideration in the care of women laboring in the ED. The machinery for both technologies is portable and easy to use, making them attractive to the emergency physician.24,25 These modalities can provide real-time information helpful for diagnosing fetal distress and assisting with intrapartum decision making.

**Electronic Fetal Monitoring.** Intrapartum assessment by electronic fetal monitoring is most useful during stage 1 of labor. Electronic fetal monitoring confirms labor and may help diagnose fetal distress. Tracings of fetal heart rate and uterine activity provide information that, when combined with clinical data, can presage fetal damage and provide a window for intervention.

Uterine activity is measured transabdominally via a pressure transducer, creating a recording of the contraction frequency. Because the measurements are indirect, the strength of the contractions correlates poorly with the tracing. The tracings are position and placement sensitive. Documentation of organized cyclic uterine contractions confirms the onset of labor and rules out Braxton Hicks contractions that are too disorganized to register in this manner. Premature onset of labor can also be diagnosed. Finally, this type of external electrical monitoring may be used to determine the efficacy of administered tocolytic agents.

Fetal heart rate tracings have several components that can be assessed: baseline heart rate, variability, accelerations, decelerations, and diagnostic patterns. Baseline heart rate, by definition, is maintained for 15 minutes in the absence of a uterine contraction and is the most important aspect of fetal heart rate monitoring.

Variability can be instantaneous (beat-to-beat) or long term over intervals of 1 minute or more. Both types of variability are indicators of fetal well-being. Accelerations of heart rate are an important component of long-term variability. Accelerations occur during fetal movement and reflect an alert, mobile fetus. Brief periods of umbilical cord compression also can cause accelerations by decreasing the venous return and reflexively generating fetal tachycardia. Meanwhile, decreased variability may indicate fetal acidemia and hypoxemia or may be a side effect of a wide array of drugs. Analgesics, sedative-hypnotics, phenothiazines, and alcohol have all been reported to cause decreased variability.

Decelerations in fetal heart rate are more complicated, and their interpretation must be integrated with the clinical situation. There are three types of deceleration: variable, early, and late (Fig. 179-6). These terms refer to the timing of the deceleration relative to the uterine contraction.

Variable and early decelerations are common. Present on more than 50% of all tracings, these heart rate changes can represent physiologic reflexes associated with head compression in the birth canal or intermittent umbilical cord compression. Variable decelerations that are persistent and repetitive usually indicate repeated episodes of umbilical cord compression. The resultant hypoxia and acidosis may cause fetal distress. Attempts to shift maternal and fetal weight off the umbilical cord by changing position are indicated. If these variable decelerations continue, the situation calls for efforts to hasten the delivery or, if obstetric backup becomes available, to perform an emergency cesarean section.

Late decelerations are more serious and most often indicate uteroplacental insufficiency. The tracing contours are generally smooth, with the heart rate nadir occurring well after maximal uterine contraction. The lag, slope, and magnitude of late decelerations correlate with increasing fetal hypoxia. Late decelerations are particularly ominous in association with poor variability, nonreactivity, and baseline bradycardia. Immediate delivery to prevent further hypoxia is indicated when these findings are present. The need for newborn resuscitation should be anticipated and preparation for critical care established for these deliveries. Overall, 30% of infants with late decelerations have good outcomes. The remaining 70% have suboptimal outcomes related to either the underlying pathologic condition or hypoxia.

Finally, the clinician should be aware of the significance of sinusoidal tracings. Tracings of this type have low baseline heart rates and little beat-to-beat variability. The sinusoidal tracing is an ominous finding that is often premorbid. The differential diagnosis includes erythroblastosis fetalis, placental abruption, fetal hemorrhage (trauma), and amnionitis.

**Ultrasoundography.** Ultrasonographic techniques have wide application in obstetric care. In the third trimester or during labor, ultrasonography can provide crucial information pertaining to impending delivery. When a technician and radiologist are available, the gestational age, biophysical profile, amniotic fluid index, as well as a survey of fetal and placental anatomy may be discerned (Table 179-1).25-27 The parameters of

THIRD-TRIMESTER ULTRASOUND: POSSIBLE INDICATIONS

- Determine number of fetuses
- Establish fetal presentation
- Identify fetal heart motion
- Locate placenta
- Measure amniotic fluid
- Determine gestational age
- Survey fetal anatomy
- Diagnose cord prolapse
- Diagnose third-trimester bleeding
- Rule out abruptio

immediate interest in the ED are fetal viability (specifically in utero gestation and fetal heart rate), lie, and presentation. Ultrasonography may also reveal multiple gestations, allowing for preparation and early communication with other specialists (from obstetrics, neonatology, and anesthesia). In 1991, the American College of Obstetricians and Gynecologists made recommendations regarding the indications for ultrasonography in the third trimester (Box 179-2). A 2- to 5-MHz transducer is appropriate for all bedside transabdominal sonographic assessments. Transvaginal ultrasonography is relatively contraindicated in the peripartum period, particularly in the cases of premature rupture of membranes and placenta previa.

Delivery. As stage 2 of labor progresses, preparation for delivery should be underway. A radiant warmer should be available and heated. Neonatal resuscitation adjuncts, such as a towel, scissors, umbilical clamps, bulb suction, airway management equipment (oxygen, bag/mask device with appropriate-sized masks, and endotracheal intubation and suctioning equipment for meconium), and equipment to achieve vascular access, masks, and endotracheal intubation and suctioning equipment should be underway. A radiant warmer should be available. Neonatal resuscitation adjuncts, such as a towel, scissors, umbilical clamps, bulb suction, airway management equipment (oxygen, bag/mask device with appropriate-sized masks, and endotracheal intubation and suctioning equipment for meconium), and equipment to achieve vascular access, masks, and endotracheal intubation and suctioning equipment should be available. Most deliveries require only basic equipment to cut and clamp the umbilical cord, suction the mouth and nose, and dry and stimulate the infant. A nurse should be at the bedside to coach and provide reassurance to the mother.

The mother should be placed in the dorsal lithotomy position and prepared for delivery. The Sims position, or left lateral position with knees drawn toward the mother’s chest and back to the physician, is also an acceptable position for delivery. The vulva and perineum are cleared and gently scrubbed, directing all mucoid debris and feces away from the introitus. A repeat sterile examination to assess labor progression and confirm presentation may be performed. Some firm digital stretching of the perineum, particularly posteriorly, may prevent tears and lacerations later in delivery.

Controlled, coordinated expulsion with coaching to sustain each push aids with crowning and delivery of the head. When the fetus is crowning, care should be exercised to have the delivery occur in a slow, controlled manner. Precipitous delivery is more likely to cause maternal injuries, such as perineal, rectal, urethral, labial, vaginal, and uterine lacerations, and fetal injuries. The most vulnerable moment is when the fetal head begins to stretch and distend the perineum. Instructing the mother to pant and not push slows the passage of the head and the shoulders as indicated. Calm communication between the physician and the mother is the best way to maintain control of the delivery. With a controlled delivery, routine performance of an episiotomy is not recommended. Instead, use of the modified Ritgen maneuver facilitates most normal deliveries.

In the modified Ritgen maneuver, a towel-draped, gloved hand is used to stretch the perineum and gently exert pressure on the chin of the fetus. The second hand puts pressure on the occiput superiorly, guiding the head into slight extension. When at the perineum, this slight extension of the head promotes delivery by positioning the head so that its smallest diameter passes through the pelvic outlet and perineum.

After the head is delivered, the physician should allow the head to rotate toward the maternal thigh and clear the fetal face and airway. Bulb suctioning of the nares and oropharynx optimally is done before proceeding with the delivery. Clearing the oropharynx at this time minimizes the likelihood of aspiration of blood, meconium, and debris collected during descent through the birth canal. Coordination with the mother is important to prevent uncontrolled fetal expulsion.

Next, the shoulders, usually anterior shoulder first, clear the perineum. The shoulders often deliver spontaneously, with little effort by the physician. First, gentle downward traction on the head promotes delivery of the anterior shoulder. A subsequent upward motion pulls the posterior shoulder through the pelvic outlet, minimizing maternal trauma. If delay occurs in delivery of the shoulders, the potential for shoulder dystocia should be considered.

As the infant clears the perineum, attention focuses on the umbilical cord. The infant should be kept low or at the level of the perineum to promote blood flow into the infant from the placenta. The cord is clamped and cut. Clamps should be placed 4 or 5 cm apart, with the proximal clamp 10 cm from the infant’s abdomen. An adequate umbilical stump is important for venous access if the child requires resuscitation.

The infant is now clear of the mother and can be wrapped in towels and moved to the warmer. Gentle drying with a towel and suctioning usually provide adequate respiratory stimulation. If not, flicking the soles of the feet and rubbing the back are other modalities. Apgar scores at 1, 5, and 10 minutes after birth should be documented.

Episiotomy. Previously, the need for episiotomy in normal deliveries was an area of controversy. The original potential benefit of episiotomy included the substitution of a straight surgical incision for a ragged, uncontrolled traumatic laceration. Theoretically, the surgical approach decreased the incidence of severe rectovaginal tears. This rationale led to widespread routine episiotomy, with a medial incision used in the United States and a mediolateral incision used in the Commonwealth countries.

Recent literature has shown that both types of incisions increase maternal morbidity and are no longer recommended for uncomplicated deliveries. Women receiving episiotomies have been shown to have a higher incidence of perineal trauma and maternal blood loss during delivery and more pelvic pain, sexual dysfunction, and urinary incontinence in the postpartum period.

Episiotomy should be performed only for specific indications, such as shoulder dystocia or breech delivery. When the decision is made to use an episiotomy, the procedure should be done before excessive stretching of the perineal muscles occurs but near the time of delivery to avoid excessive bleeding. Common practice is to cut the episiotomy when the head is visible during a contraction and the introitus opens to a diameter of 3 or 4 cm. Most authors currently recommend a mediolateral incision to avoid perineal tears and rectal involvement; this is particularly true for a complicated delivery in which lacerations extending the surgical incision are likely (Fig. 179-7).
Table 179-2 summarizes some of the adjuncts used in normal labor and delivery, with recommendations regarding their use in the high-risk setting of an ED delivery.

### Third Stage of Labor

The third stage of labor involves the delivery of the placenta and is a time of patient observation with frequent checks of the tone and height of the uterine fundus. Signs of placental separation include the following:

1. The uterus becomes firmer and rises.
2. The umbilical cord lengthens 5 to 10 cm.
3. There is a sudden gush of blood.32

These signs usually occur within 5 to 10 minutes of the delivery of the infant but may extend to 30 minutes. Beyond 18 minutes, the risk of postpartum hemorrhage increases and is, in fact, up to six times more likely after 30 minutes.33 Although the placenta may be delivered expectantly, active management reduces the length of the third stage of labor and thereby decreases the risk of postpartum hemorrhage. Active management includes the administration of uterotonics, gentle traction of the clamped umbilical cord with mild pressure applied above the symphysis pubis, and uterine massage after delivery.34 Be aware that any attempt to deliver the placenta before it separates is contraindicated.

Examination of the placenta and umbilical cord is an essential part of the delivery process. Abnormalities of the cord should be noted at this time. Also, a segment of the umbilical cord should be kept available as a source of cord blood.

Normally a three-vessel structure, the umbilical cord is filled with a connective tissue known as Wharton’s jelly and is approximately 50 to 60 cm long and 12 mm in diameter. Normal architecture places the two umbilical arteries on either side of the single umbilical vein. A two-vessel cord (one umbilical artery) occurs in 1 of 500 deliveries, is more common in African Americans, and is a result of aplasia or atrophy. Approximately

IV, intravenous; NPO, nothing by mouth.
30% of two-vessel cord infants have congenital defects. An association also exists between fetal structural anomalies and placental vascular occlusion or thrombosis.35

The placenta should also be examined for abnormalities. Clots adherent to the uterine aspect may indicate placental abruption. Accessory lobes (succecentiurate placenta if completely separate) and abnormal cord insertion are common abnormalities. The umbilical cord and placenta routinely should be held for pathologic review.36 The discovery of an incomplete placenta or membranes should alert the emergency physician to the possibility of postpartum complications and should be documented.

Fourth Stage of Labor

The fourth stage of labor refers to the first hour after delivery of the placenta and is a critical period because postpartum hemorrhage is most likely to occur during this time. Thus, careful examination and repair of any vaginal lacerations should be performed. The cervix and vaginal fornices should be visually inspected to avoid missing deep lacerations as a result of delivery.

At this point, oxytocin is infused to promote contraction of the uterus and control hemorrhage. The uterus should be evaluated frequently for tone and massaged transabdominally if any sign of relaxation exists. Oxytocin should not be given before delivery of the placenta because this may result in the trapping of placental fragments or may hinder the delivery of an undetected twin.

The differentiation of false labor (Braxton Hicks contractions) from true labor is best done by electrical monitoring. Ultrasonography may also aid in the diagnosis because fetal breathing movements make the diagnosis of false labor unlikely. The initial evaluation of a woman with possible preterm labor should include urinalysis, complete blood count, and pelvic ultrasonography. If delivery is not imminent, these studies can be performed in the ED or obstetrics area, whichever would provide the best monitoring. When possible, these patients should be transferred to a perinatal center with an associated intensive care unit.

**Management.** A viable fetus and healthy mother are indications for medical management directed toward the prolongation of gestation. Preterm labor should not be postponed with medical management in the cases of intrauterine demise, major congenital anomalies, eclampsia, or, most important, PROM.38 When patients with PROM, fetal disorders, and maternal contraindications are excluded, only one fourth of all women in premature labor are candidates for medical management.39

The treatment of preterm labor involves multiple modalities. Tocolytics to palliate labor and fetal maturation therapy combined with bedrest and hydration are used in hopes of prolonging pregnancy (Box 179-4). These patients optimally should be transferred to an appropriate center before delivery whenever possible because medical management fails in more than 25% of preterm patients in whom it is attempted.40

**Tocolysis.** The two classically used tocolytics were magnesium sulfate and beta-mimetic drugs. Other medications that have been shown to be as or more effective include prostaglandin synthetase inhibitors (nonsteroidal anti-inflammatory drugs [NSAIDs]) and calcium channel blockers.41,42 When indicated and in coordination with an obstetric consultant, tocolytics initiated in the ED may arrest premature labor, preventing imminent delivery in 75 to 80% of patients for 48 to 72 hours.42

**Magnesium Sulfate.** Magnesium sulfate competitively inhibits calcium uptake into smooth muscle and allows relaxation. Women treated with magnesium require monitoring. Magnesium produces respiratory and neurologic depression at elevated levels, exacerbated by renal insufficiency. Pulmonary edema and cardiac dysrhythmias have also been reported. These effects can be reversed rapidly by the administration of calcium-containing solutions (i.e., 1 g of 10% calcium gluconate solution). Because women with premature labor are at risk for ascending infections, early treatment with antibiotics is often indicated during magnesium therapy (Table 179-3).43

**Beta-Mimetics.** Beta-mimetics (ritodrine and terbutaline) cause smooth muscle relaxation by activating enzymes that bind calcium to the sarcoplasmic reticulum. This effect is mediated by beta1-receptors that increase cyclic adenosine monophosphate concentrations in the myometrium. The beta-mimetic is titrated to effect since the dosage needed to eliminate uterine activity is unpredictable and varies. Only side effects limit beta-mimetic administration. They freely cross the placenta and cause fetal tachycardia. In one meta-analysis, beta-mimetics and magnesium sulfate had similar efficacy in eliminating contractions.42

Pulmonary edema is the main adverse effect of high-dose beta-mimetics. This complication is more likely to occur in mothers with preexisting cardiac disease, multiple gestations, and maternal infection. This form of pulmonary edema is high-output failure and tends to occur when there is sustained maternal tachycardia greater than 120 beats/min. Beta-mimetics should be gradually titrated according to uterine activity and maternal heart rate. Eventually, tachyphylaxis and receptor down-regulation decrease the effectiveness of these drugs over 24 to 48 hours.40

Beta1-related side effects can be problematic in diabetic mothers. Beta1 stimulation can lead to diabetic ketoacidosis and the usual cascade of metabolic and electrolyte abnormalities.41 Surveillance of the urine for glucose and ketones is recommended. Fetal heart stimulation may result in increased cerebral perfusion pressures. A premature infant’s central nervous system vasculature is delicate and may not tolerate these changes. Beta-mimetics are associated with an increased incidence of fetal intraventricular hemorrhage.45

**NSAIDs.** The prostaglandin synthetase inhibitors, specifically indomethacin and sulindac, have been shown to be as or more effective than magnesium and the beta-mimetics in multiple trials. However, in the fetus, pulmonary hypertension, patent ductus arteriosus constriction, renal insufficiency, necrotizing enterocolitis, and intraventricular hemorrhage have been reported with NSAID use. Potential maternal side effects include a prolonged bleeding time and renal insufficiency.43,46

**Calcium Channel Blockers.** Calcium channel blockers have also been used as tocolytics with success. Nifedipine or nicardipine may be given. Onset is more rapid than that of magnesium, and the maternal and fetal side effect profiles are good.41,42

Aggressive titratable tocolytics are best for the initial 24 to 48 hours of preterm labor. After uterine contractions have been stopped, the patient can usually be maintained on oral agents, although the benefits of maintenance tocolysis, studied to date primarily with beta-mimetics and magnesium, have yet to be shown.42 The contraindications to tocolytics are important to review before initiating these therapies (Box 179-5). Any patient receiving tocolytics should be externally monitored (electrically) for signs of fetal distress.

**Premature Rupture of Membranes**

**Clinical Features.** PROM, also known as *amniorrhesis*, is defined as rupture of the amniotic and chorionic membranes before the onset of labor. PROM affects 3% of all gestations.45 During pregnancy, the chorionic and amniotic membranes protect the fetus from infection and provide an environment that allows fetal growth and movement. The amniotic fluid is constantly exchanged by fetal swallowing and urination and umbilical cord transfer. The fetal airway also contains a secreted fluid that allows for fetal breathing movements, promoting fetal...
respiratory development. This fluid is produced at 5 mL/kg/hr at term gestation and is resorbed rapidly by the pulmonary lymphatics, blood vessels, and upper airway at birth.

The word *premature* in PROM refers to rupture before labor, not to fetal prematurity. In 10 to 15% of PROM cases, the fetus is at or near term, and PROM may result in normal labor. When PROM is associated with fetal prematurity, there is significant fetal morbidity and mortality. PROM is the inciting event in one third of all preterm deliveries.

After the membranes rupture, the period from latency to the onset of labor varies. Longer latent periods are common earlier in pregnancy, and the latency shortens as gestational age increases. At term, labor is a desirable result of PROM, but with fetal immaturity labor is problematic because delivery would result in fetal complications, such as hyaline membrane disease.

**Diagnostic Strategies.** The diagnosis of PROM usually can be established by history and physical examination. The patient usually describes a spontaneous gush of watery fluid followed by a mild persistent seepage. In most cases, the patient suggests the diagnosis and usually is correct. Urinary incontinence or excess vaginal or cervical secretions are occasionally confused with PROM.

Examination of women with potential PROM should be performed under sterile conditions to prevent ascending infection. Direct digital examination of the cervix should be avoided. The incidence of infection has been shown to be proportional to the number of examinations. The identification of amniotic fluid was previously discussed. Table 179-4 summarizes the bedside testing modalities available to confirm the diagnosis of PROM. Visualization of the cervix for prolapsed cord or abnormal fetal presentation (prolapse of a small part) should be done during the uterine evaluation for effacement and dilation. Cultures for group B streptococci, *Chlamydia*, and gonorrhea should be obtained.

**Management.** When the diagnosis of PROM is established, management depends on several factors: gestational age and maturity of fetus, the presence of active labor, the presence or absence of infection, the presence of placental abruption, and the degree of fetal well-being or distress. Obstetric consultation and admission are indicated.

Gestational age may be well known by menstrual history and previous ultrasonographic scans. In the absence of such data, immediate ultrasonography provides an estimated gestational age quickly. Fetal maturity is a more complex determination. Beyond 36 weeks of gestation, fetal pulmonary maturity is likely. If the gestational age is less than 36 weeks, testing the amniotic fluid for the lecithin-to-sphingomyelin ratio or for phosphatidylglycerol can establish maturity. Fluid pooling in the posterior vaginal vault can be used for this purpose.

In the immature fetus (24–31 weeks of gestation), administration of corticosteroids can accelerate pulmonary maturation. The benefit of this strategy has been shown with preterm labor; however, this therapy is less well documented for PROM. In PROM, treatment with steroids seems to decrease the incidence and severity of hyaline membrane disease, but it may increase the risk of maternal infectious complications. Rupture of the membranes also stimulates fetal lung maturation, making it more difficult to establish a treatment benefit in PROM compared with preterm labor. When gestational age is less than 26 weeks, the latent interval to delivery is often 1 week. Tocolytics are an obvious choice, but their use is controversial. When tocolytics are used, the goal is to temporize, allowing time for therapy to take effect. These treatment decisions should be coordinated with the receiving obstetrician.

All patients with PROM should be assessed for intra-amniotic infection. Infectious complications should be diagnosed and treated before the mother develops overt clinical signs of infection. Preterm PROM is usually treated with intravenous penicillin and erythromycin. Treatment of term PROM is indicated when the patient is group B streptococcus positive or has not been tested. The signs and symptoms of chorioamnionitis are late manifestations of advanced infection and are discussed next.

**Chorioamnionitis**

Chorioamnionitis occurs when vaginal or cervical bacteria ascend into the uterus, instigating an inflammation of the chorion and amnion layers of the amniotic sac. It occurs in 1 to 10% of all pregnancies, and risk factors include prolonged labor, premature rupture of membranes, excessive vaginal examinations, and recent amniocentesis. Box 179-6 summarizes bacterial and viral causes of PROM.

Vertical Transmission of Human Immunodeficiency Virus

Emergency deliveries may involve women who are known to be HIV positive in addition to women who are infected but have never been tested. The latter group generally includes pregnant women with little or no prenatal care who are at risk for precipitous delivery. Transmission may occur in the antepartum, intrapartum, or postpartum period (breast-feeding). Because intrapartum transmission accounts for up to 75% of vertically transmitted HIV infections, antiretroviral therapy upon presentation, even while labor progresses, can decrease vertical HIV transmission. Potential mechanisms of transmission include microtransfusion during contractions, absorption of virus through the mucous membranes, and even invasion through the epithelium. Risk factors for transmission include high viral loads, prolonged rupture of membranes, maternal drug use, vaginal delivery, and breast-feeding (Table 179-4).53,54

In November 2002, the Food and Drug Administration approved the OraQuick Rapid HIV-1 Antibody Test (OraSure Technologies, Bethlehem, Pa).55 Point-of-care testing for HIV with a median turnaround time of 45 minutes realistically allows the clinician to initiate intrapartum and neonatal antiretroviral treatment upon presentation.56 Since 1994, it has been known that immediate treatment during labor can significantly decrease vertical transmission to the newborn.57,58

A positive HIV test in some cases may allow for a change in the method of delivery. Cesarean section decreases the rate of HIV transmission compared with vaginal delivery methods. In a 1999 meta-analysis from the United States and Europe, vertical HIV transmission was decreased by cesarean section with an odds ratio of 0.43 (95% confidence interval, 0.33–0.56). The protective effect of surgical delivery over other delivery methods persisted even when the data were stratified for the method of delivery. Cesarean section decreases the rate of primary cesarean sections. Because rapid surgical resolution is unavailable to the emergency physician, intrapartum management skills are important.

Principles of Disease

Knowledge of abnormal labor and its anatomy and physiology is important for the clinician facing a complicated delivery. Intrapartum management skills will enable the emergency physician to proceed with delivery in an efficient, capable manner.

Dystocia and Malpresentation. Dystocia, or abnormal labor progression, accounts for one third of all cesarean sections and half of primary cesarean sections. Because rapid surgical resolution is unavailable to the emergency physician, intrapartum management skills are important. Dystocia can be divided into three etiologic categories. Labor fails to progress when there are problems related to the pelvic architecture (the passage), when there are fetal size or presentation problems (the passenger), and when uterine expulsive forces are inadequate. Although it is useful to consider these causes independently, dystocia is usually caused by a combination of factors. Presentation problems are particularly important because they become apparent during stage 2 of labor and require immediate action.

In order of increasing incidence, brow, face, shoulder, and breech presentations are the most common malpresentations (Table 179-5). True fetopelvic disproportion is much less common. Cesarean section is indicated when labor arrest or cord prolapse coexists with these presentations.64

Breech Delivery

Perspective. Breech is the most common malpresentation, occurring in approximately 4% of all deliveries. Three types of breech presentation exist: frank, incomplete, and complete (Fig. 179-8; Box 179-7). The main mechanical problem with breech presentations is that the buttocks and legs do not provide a sufficient wedge, hindering cervical accommodation of the relatively larger head. In addition, because the presenting part does not completely occlude the cervical opening, umbilical cord prolapse may occur.

The terminology for breech deliveries is complicated. By convention, the presentation (frank, incomplete, and complete) is followed by the relationship of the fetus to the birth canal, using the fetal sacrum as a reference point. The mode of delivery used also has specific terminology. Spontaneous breech delivery refers to vaginal delivery without manual aid.

</tbody>
</table>

**Box 179-7**

**BREECH PRESENTATIONS**

**Frank Breech**
- 60–65% of all breech presentations
- Hips flexed, knees extended
- Buttocks act as good dilating wedge
- Incidence of cord prolapse approximately 0.5%

**Complete Breech**
- Least common, occurs in approximately 5% of all breech presentations
- Hips and knees flexed
- Buttocks act as good dilating wedge
- Incidence of cord prolapse is 5–6%

**Incomplete Breech**
- 25–35% of all breech presentations
- Incomplete hip flexion, single or double footling
- Poor wedge
- Increased incidence of prolapsed cord (15–18%)

Almost always of a small premature infant. *Assisted breech delivery* and *partial breech extraction* are terms that apply when delivery is manually assisted after the umbilicus clears the perineum. The head may be delivered by intrapartum maneuvers or forceps. *Complete breech extraction* consists of the application of traction to the lower extremities or groin before delivery of the buttocks. This approach is never indicated for a singleton breech because it increases the chances of head entrapment. Confusion arises because the word *complete*, as used here, describes the mode of delivery, not the presentation.

Slightly less than 4% of deliveries are breech. Correlated with this abnormal presentation are several factors: prematurity, multiparity, fetal abnormalities, prior breech presentation, polyhydramnios, and uterine abnormalities.65

Overall, one third of breech fetal deaths are believed to be preventable. Asphyxia is often due to umbilical cord prolapse or entrapment of the head. Fetal head and neck trauma can occur if inappropriate delivery techniques are used. Scheduled cesarean section for these patients reduces the potential for emergency room presentation. Since the 1990s, however, obstetricians have been attempting to decrease cesarean rates. As part of this process, some centers have proposed a trial of labor and vaginal delivery for selected full-term infants with frank breech presentations.66 Therefore, the potential for the emergency physician to encounter a breech presentation may be increasing.

**Diagnostic Strategies.** Before labor, Leopold’s maneuvers facilitate the diagnosis of breech presentation. In the case of breech presentation, Leopold’s first maneuver identifies a firm, round mass (the head) in the fundus of the uterus. The third maneuver reveals the softer breech at the pelvic inlet. For the emergency physician, active labor restricts the use of Leopold’s maneuvers; thus, vaginal examination is required.

The differentiation of a vertex presentation from a breech by tactile vaginal examination is not always simple. Any time...
a fontanelle is not identified on examination, a breech presentation should be suspected. During the vaginal examination, it is helpful to remember that the face and the skull have a complete circle of bone, whereas the anus is flanked by bone on only two sides.

If time allows, immediate ultrasonographic studies or plain radiographs are indicated to obtain information on the position of the fetal arms and neck. If the fetus has a hyperextended neck, vaginal delivery is associated with a 70% incidence of spinal cord injuries. If possible, labor should be delayed to allow cesarean section. Likewise, if the arms are over the head, they increase the dystocia when the head enters the birth canal. If ultrasound reveals anencephaly or massive hydrocephaly, vaginal breech delivery should be allowed to continue in order to avoid cesarean section.

Management. Premature infants in the breech position often deliver spontaneously without difficulty. As the infant comes to term, dystocia becomes increasingly common. When committed to a vaginal delivery, knowledge of breech dystocia mechanics may allow atraumatic delivery. The key goals are to maximize the size of the passage and to minimize the dystocia of the aftercoming head. Box 179-8 summarizes the actions associated with successful vaginal breech delivery.

The Mauriceau maneuver is the use of the fetal oral aperture to flex the fetal neck and draw it in the chin. Because fetal neck extension is associated with cord injuries and worsening dystocia, this maneuver is crucial to successful vaginal delivery. While the Mauriceau maneuver is used, the fetal pelvis should be supported to avoid abdominal injuries. Generous episiotomy may even be necessary to facilitate the Mauriceau maneuver in a full-term infant. If the aftercoming head cannot be delivered quickly, the chances of good fetal outcome are poor. For term infants, labor arrest, asphyxia, and/or brachial plexus injuries can be avoided by the use of this maneuver. If time allows, immediate ultrasonographic studies or plain radiographs are indicated to obtain information on the position of the fetal arms and neck. If the fetus has a hyperextended neck, vaginal delivery is associated with a 70% incidence of spinal cord injuries. If possible, labor should be delayed to allow cesarean section. Likewise, if the arms are over the head, they increase the dystocia when the head enters the birth canal. If ultrasound reveals anencephaly or massive hydrocephaly, vaginal breech delivery should be allowed to continue in order to avoid cesarean section.

**Shoulder Dystocia**

**Perspective.** Shoulder dystocia is the second most common complication of childbirth, occurring in 1 in 300 deliveries. In contrast to a breech presentation, which may be diagnosed antepartum, shoulder dystocia develops intrapartum. Maternal and fetal factors are associated with shoulder dystocia. Maternal factors include diabetes, obesity, and prolonged second stage of labor; fetal factors include macrosomia, postmaturity, and erythroblastosis fetalis. The combination of prenatal data, estimated fetal weight, and fetal biometry cannot reliably identify most deliveries complicated by shoulder dystocia. The fact that shoulder dystocia responds well to a variety of intrapartum maneuvers means that delivery skill is an important determinant of fetal outcome.

The consequences of shoulder dystocia can be devastating. As with breech presentation, infant complications are more common and severe than maternal complications. Asphyxia, traumatic brachial plexus injuries, and humeral and clavicular fractures contribute to a complication rate of 20%. Maternal complications are related to traumatic delivery and include vaginal, perineal, and anal sphincter tears as well as urinary incontinence.

**Diagnostic Strategies.** Shoulder dystocia is diagnosed clinically by the inability to deliver either shoulder. The fetal head may appear to retract toward the maternal perineum. This finding is known as the “turtle sign.” Traction on the head extends and abducts the shoulders, increasing the bisacromial diameter and worsening the dystocia. Figure 179-9 shows the normal and abnormal relationship of the shoulders to the birth canal and illustrates why the bisacromial diameter is an important element of fetal biometry.

Normally, the shoulders negotiate the maternal pelvis in a sequential fashion, anterior shoulder first. With shoulder dystocia, both shoulders attempt to clear the maternal pelvis simultaneously. In addition to the turtle sign, examination often reveals that the fetal shoulders are on a vertical axis (rather than oblique). These findings in combination with an arrested delivery confirm the diagnosis of shoulder dystocia.

**Management.** When shoulder dystocia becomes evident, knowledge of intrapartum delivery maneuvers can be lifesaving. Successful vaginal delivery is most likely when a directed sequential approach to each maneuver is used. Rapid resolution of shoulder dystocia is important to avoid fetal asphyxia and resultant central nervous system injury. A head-to-body time interval over 6 to 8 minutes is considered critical in the development of these sequelae. Obstetric and neonatology assistance may improve the outcome, and aggressive attempts to obtain help in these areas are warranted.

Initial attempts to resolve shoulder dystocia involve increasing the anteroposterior diameter of the passage. An episiotomy may be used for fetal maneuvering by allowing access to the posterior shoulder. Anteriorly, draining the bladder with a Foley catheter can generate room.

The most important first step is to use the McRoberts’ maneuver (Fig. 179-10). Maternal leg flexion to a knee-chest position may disengage the anterior shoulder, allowing rapid vaginal delivery to follow. This maneuver “walks” the pubic symphysis over the anterior shoulder and flattens the sacrum, helping the fetus to pass through the birth canal one shoulder at a time. This method, although requiring very little effort, is successful in 40% of shoulder dystocia cases when used alone.

If the McRoberts’ maneuver does not free the anterior shoulder, suprapubic pressure may accomplish the goal. Pressure may slip the anterior shoulder beneath the pubis or cause the posterior shoulder to retreat into the hollow of the sacrum. Digital pressure on the posterior shoulder (via the episiotomy) may help facilitate posterior shoulder retreat.

**BOX 179-8 VAGINAL BREECH DELIVERY**

**Actions to Do as Able**
- Monitoring fetal heart rate
- Focused history
- Diagnosis of breech lie
- Cervical dilation and station determination
- Ultrasonography or plain radiography
- Evaluation for prolapsed cord if spontaneous rupture of membranes
- Episiotomy
- Knee flexion and sweep out legs
- Pulling out a 10- to 15-cm loop of cord (room to work) after umbilicus clears perineum
- Use of bony pelvis as means of holding infant
- Keeping face and abdomen away from symphysis, and using rotation to deliver the more accessible arm
- Mauriceau maneuver

**Actions to Avoid**
- Inappropriate transfer with delivery en route
- Misdiagnosis of cervical dilation
- Iatrogenic rupture of membranes (cord prolapse)
- Moving patients or leaving unmonitored
- Traction on the fetus during delivery
- Grasping fetus by the waist, causing abdominal organ injury
- Arm entrapment over head
- Neck hyperextension

**Management.** Premature infants in the breech position often deliver spontaneously without difficulty. As the infant comes to term, dystocia becomes increasingly common. When committed to a vaginal delivery, knowledge of breech dystocia mechanics may allow atraumatic delivery. The key goals are to maximize the size of the passage and to minimize the dystocia of the aftercoming head. Box 179-8 summarizes the actions associated with successful vaginal breech delivery.

The Mauriceau maneuver is the use of the fetal oral aperture to flex the fetal neck and draw it in the chin. Because fetal neck extension is associated with cord injuries and worsening dystocia, this maneuver is crucial to successful vaginal delivery. While the Mauriceau maneuver is used, the fetal pelvis should be supported to avoid abdominal injuries. Generous episiotomy may even be necessary to facilitate the Mauriceau maneuver in a full-term infant. If the aftercoming head cannot be delivered quickly, the chances of good fetal outcome are poor. For term infants, labor arrest, asphyxia, and/or brachial plexus injuries can be avoided by the use of this maneuver.

**Shoulder Dystocia**

**Perspective.** Shoulder dystocia is the second most common complication of childbirth, occurring in 1 in 300 deliveries. In contrast to a breech presentation, which may be diagnosed antepartum, shoulder dystocia develops intrapartum. Maternal and fetal factors are associated with shoulder dystocia. Maternal factors include diabetes, obesity, and prolonged second stage of labor; fetal factors include macrosomia, postmaturity, and erythroblastosis fetalis. The combination of prenatal data, estimated fetal weight, and fetal biometry cannot reliably identify most deliveries complicated by shoulder dystocia. The fact that shoulder dystocia responds well to a variety of intrapartum maneuvers means that delivery skill is an important determinant of fetal outcome.

The consequences of shoulder dystocia can be devastating. As with breech presentation, infant complications are more common and severe than maternal complications. Asphyxia, traumatic brachial plexus injuries, and humeral and clavicular fractures contribute to a complication rate of 20%. Maternal complications are related to traumatic delivery and include vaginal, perineal, and anal sphincter tears as well as urinary incontinence.

**Diagnostic Strategies.** Shoulder dystocia is diagnosed clinically by the inability to deliver either shoulder. The fetal head may appear to retract toward the maternal perineum. This finding is known as the “turtle sign.” Traction on the head extends and abducts the shoulders, increasing the bisacromial diameter and worsening the dystocia. Figure 179-9 shows the normal and abnormal relationship of the shoulders to the birth canal and illustrates why the bisacromial diameter is an important element of fetal biometry.

Normally, the shoulders negotiate the maternal pelvis in a sequential fashion, anterior shoulder first. With shoulder dystocia, both shoulders attempt to clear the maternal pelvis simultaneously. In addition to the turtle sign, examination often reveals that the fetal shoulders are on a vertical axis (rather than oblique). These findings in combination with an arrested delivery confirm the diagnosis of shoulder dystocia.

**Management.** When shoulder dystocia becomes evident, knowledge of intrapartum delivery maneuvers can be lifesaving. Successful vaginal delivery is most likely when a directed sequential approach to each maneuver is used. Rapid resolution of shoulder dystocia is important to avoid fetal asphyxia and resultant central nervous system injury. A head-to-body time interval over 6 to 8 minutes is considered critical in the development of these sequelae. Obstetric and neonatology assistance may improve the outcome, and aggressive attempts to obtain help in these areas are warranted.

Initial attempts to resolve shoulder dystocia involve increasing the anteroposterior diameter of the passage. An episiotomy may be used for fetal maneuvering by allowing access to the posterior shoulder. Anteriorly, draining the bladder with a Foley catheter can generate room.

The most important first step is to use the McRoberts’ maneuver (Fig. 179-10). Maternal leg flexion to a knee-chest position may disengage the anterior shoulder, allowing rapid vaginal delivery to follow. This maneuver “walks” the pubic symphysis over the anterior shoulder and flattens the sacrum, helping the fetus to pass through the birth canal one shoulder at a time. This method, although requiring very little effort, is successful in 40% of shoulder dystocia cases when used alone.

If the McRoberts’ maneuver does not free the anterior shoulder, suprapubic pressure may accomplish the goal. Pressure may slip the anterior shoulder beneath the pubis or cause the posterior shoulder to retreat into the hollow of the sacrum. Digital pressure on the posterior shoulder (via the episiotomy) may help facilitate posterior shoulder retreat.

**BOX 179-8 VAGINAL BREECH DELIVERY**

**Actions to Do as Able**
- Monitoring fetal heart rate
- Focused history
- Diagnosis of breech lie
- Cervical dilation and station determination
- Ultrasonography or plain radiography
- Evaluation for prolapsed cord if spontaneous rupture of membranes
- Episiotomy
- Knee flexion and sweep out legs
- Pulling out a 10- to 15-cm loop of cord (room to work) after umbilicus clears perineum
- Use of bony pelvis as means of holding infant
- Keeping face and abdomen away from symphysis, and using rotation to deliver the more accessible arm
- Mauriceau maneuver

**Actions to Avoid**
- Inappropriate transfer with delivery en route
- Misdiagnosis of cervical dilation
- Iatrogenic rupture of membranes (cord prolapse)
- Moving patients or leaving unmonitored
- Traction on the fetus during delivery
- Grasping fetus by the waist, causing abdominal organ injury
- Arm entrapment over head
- Neck hyperextension
Use of these intrapartum maneuvers resolves most cases of shoulder dystocia. However, if delivery is still impossible, more drastic interventions are warranted. Decreasing the bisacromial diameter may be possible by pushing the most accessible shoulder toward the fetal chest (Rubin’s maneuver; Fig. 179-11). Often, both shoulders assume the same attitude, decreasing the bisacromial diameter and allowing delivery. Attempts to manipulate the shoulders for Rubin’s maneuver may be transabdominal, via the introitus (anterior shoulder), or via the episiotomy (posterior shoulder).

If the shoulders remain undeliverable, the next step is to use Wood’s corkscrew maneuver. In this process, the impacted shoulders are released through rotation of the fetus 180 degrees. Fetal rotation is achieved by pushing the most accessible shoulder toward the chest. The fetal axilla can be snared with a digit, or a hand can be slid in along the fetal spine to sweep the hips and generate rotation. Wood’s corkscrew maneuver is difficult to perform but should be attempted before reaching for an arm. A slightly oblique anteroposterior position for the shoulders provides the largest passage through the pelvic outlet.

At this juncture, if the fetus remains trapped and several attempts have failed to yield delivery, consideration of delivery of an arm is appropriate. A hand is introduced along the posterior aspect of the posterior shoulder. This would be a tight fit, requiring tactile identification of fetal anatomy. The posterior arm is swept across the chest, bringing the fetal hand up to the chin. Attempts to splint the humerus may prevent fractures and brachial plexus injuries. The fetal hand is grasped and pulled out of the birth canal across the face, delivering the posterior shoulder. The mnemonic HELPER (Box 179-9) has been proposed to help keep these steps organized and to
The Pregnant Patient

Labor. Approximately half are discovered during the second stage of labor, most are discovered during labor via vaginal examination. Disposition to labor arrest. Although these abnormal presentations increases. Maternal and fetal complication rates are correspondingly higher. Incidence of preterm labor and low birth weights, both treatments. In 2003, twin deliveries accounted for 31.5 per 1000 live births. If twin A is nonvertex, cesarean section is the preferred route. In such cases, efforts to delay delivery until an operative approach option. The general consensus is that if twin A is nonvertex, cesarean section is the preferred route. In such cases, efforts should be made to delay delivery until an operative approach can be used. Proceeding vaginally can result in the “stuck twin” syndrome and lead to poor outcome. The interval between the delivery of twin A and twin B is variable. Although in most cases twin B delivers in minutes, prolonged interdelivery times with good fetal outcomes have been reported. When twin B does not follow rapidly, in utero assessment is important to document fetal well-being. If fetal heart tracings are reassuring, the delivery of twin B (especially nonvertex) should not be hastened. Repeat ultrasonographic evaluation may be utilized to confirm twin B’s presentation and well-being during the interdelivery period.

After every emergency department delivery, particularly deliveries that are precipitous or that occur in the out-of-hospital setting, the mother should be examined for the possibility of twins. Ongoing labor may be confused with postpartum cramping, only to have twin B and all of the potential complications surprise the clinician. This situation is particularly relevant for women with inadequate prenatal care and low-birth-weight infants.

Umbilical Cord–Related Emergencies

Perspective

Umbilical cord–related complications can occur in normal and abnormal deliveries. Immediate intervention is required to prevent fetal morbidity and mortality. The spectrum of cord-related emergencies includes prolapsed cord, nuchal loops of the umbilical cord, body coils, cord knots, and entangled cords in monoamniotic twins. Cord length is believed to be proportional to fetal activity in utero during the first and second trimesters. Excess cord length increases the potential for umbilical cord complications of all types. Because the umbilical cord supplies the fetus with all of its oxygen, interruption of cord circulation before establishment of fetal respiration is a life-threatening emergency. Fetal asphyxia caused by cord...
Umbilical Cord Prolapse

Clinical Features. Umbilical cord prolapse occurs when (1) the umbilical cord precedes the fetal presenting part or (2) the presenting part does not fill the birth canal completely. Most instances of cord prolapse are unexpected and develop during the second stage of labor.

Cord prolapse has a variable rate of association with different fetal presentations. Compound, shoulder, and breech presentations all yield gaps and a relatively dilating wedge. Table 179-6 summarizes the rates of umbilical cord prolapse with various fetal presentations. Overall, malpresentations account for 50% of cord prolapse cases; therefore, prolapse may be the first indication of a malpresentation. 80,81 The incidence of cord prolapse is reported to range from 0.3 to 0.6% of all deliveries and associated perinatal mortality ranges from 8.6 to 49%.80,81

Diagnostic Strategies. Umbilical cord prolapse may be overt or occult, requiring a pelvic examination to reveal the umbilical cord lying beside the presenting part. The diagnosis also may be made with Doppler ultrasonography. In most cases, the diagnosis is obvious, and the cord is encountered at the perineum or introitus.

Management. Whenever a prolapsed cord occurs with a viable infant, cesarean section is the delivery method of choice. If surgical delivery is available, maneuvers to preserve umbilical circulation should be instituted immediately. The mother should be placed in the knee-chest position with the bed in Trendelenburg as the presenting part is digitally elevated off the umbilical cord.82 It is crucial that the mother be instructed not to push, to avoid further compression of the cord. Placement of a Foley catheter and instillation of 500 to 750 mL of saline into the bladder may help lift the fetus off the cord, particularly in the first stage of labor.

Preparation for an emergency (“crash”) cesarean section should be underway. The time from prolapse to surgical intervention is an important factor in fetal outcome. Perinatal mortality rates of approximately 15% are reported for prolapsed cord deliveries; however, if cesarean section can be done within 10 minutes, the mortality rate decreases to 5%.83 These numbers have implications for the availability of obstetric and surgical backup for the ED.

If surgical delivery cannot be done in a timely fashion, funic reduction (manual replacement of the cord into the uterus) and rapid vaginal delivery may be the only options available. The same maneuvers to decrease cord compression are used, and the umbilical cord is pushed gently, in a retrograde fashion, above the presenting part. Manipulation and cord trauma should be kept to a minimum because the resultant vasospasm can cause fetal hypoxia. After funic reduction, the development of umbilical cord body coils or nuchal loops is common and should be anticipated.84

Subsequent to delivery, the physician should be prepared for resuscitation of a distressed newborn. If one is available, a neonatologist should attend the delivery.

Cord Entanglement

The umbilical cord can also become entangled with itself, spontaneously knotting. Umbilical cord knots are related to intrauterine movements early in pregnancy. Approximately 4 or 5% of stillbirths are found to have knots that are believed to have caused fetal demise. Despite this association, cord knots can persist without problems as long as perfusion is maintained.

Loose umbilical cord knots pulled tight at delivery may cause fetal distress. As with cord prolapse, this situation must be resolved quickly to prevent fetal asphyxia. Rapid delivery with avoidance of further cord traction optimizes fetal outcome. No specific interventions exist to deal with this problem.

Long umbilical cords are associated with true knots as well as entanglements and prolapse. Because the fetal limbs are short and flexed in most presentations, they are rarely involved. Loops around the neck and body do occur, however. Umbilical cord loops can be single or multiple, and there are reports of six nuchal loops. Risk factors for excessive cord length include increasing parity and fetal weight. Although generally benign, they may result in fetal complications, such as nonreassuring fetal status and respiratory distress.85

During delivery, loose nuchal cords should be reduced at the perineum. Loose body coils usually disentangle spontaneously. The reduction process may be aided by slipping them over the extremities or forward over the head. Occasionally, loops are tight enough to impede delivery and cannot be reduced. The solution is to cut the clamped cord and deliver the infant rapidly. The high frequency of nuchal loops (one in five births) means that the emergency physician should expect to encounter this problem.

Maternal Complications of Labor and Delivery

Perspective

Maternal complications of labor and delivery include postpartum hemorrhage, uterine inversion and rupture, amniotic fluid embolism, infections, and more. Many of these problems can be managed nonsurgically. When severe, however, these complications threaten the reproductive future and the life of the mother, and they may require emergent surgical intervention.

Postpartum Hemorrhage

Clinical Features. Postpartum hemorrhage is the most common complication of labor and delivery. Defined as hemorrhage greater than 500 mL, it affects 5 to 10% of all deliveries and accounts for up to 25% of obstetric deaths.86,87 Postpartum hemorrhage is divided into primary and secondary categories. The primary category includes blood loss that occurs within the first 24 hours, and the secondary category is hemorrhage 24 hours to 6 weeks after delivery. The clinical picture is as expected with any type of hemorrhage, although due to maternal adaptations during pregnancy, the patient may not show signs of shock until more than 1500 mL of volume is lost.88
Differential Considerations. The differential diagnosis of primary postpartum hemorrhage includes uterine atony, genital tract trauma, retained placental tissue, and coagulopathies, or the “four Ts”: tone, trauma, tissue, and thrombin.

Uterine Atony. The most common cause of serious immediate postpartum hemorrhage is laxity of the uterus after delivery. It accounts for 75 to 90% of postpartum hemorrhage cases. Postpartum bleeding from the placental implantation site normally is limited by contraction of the myometrium, constricting the spiral arteries. If the uterus cannot or does not contract, ongoing hemorrhage will occur. Predisposing factors include overdistention of the uterus (multiple gestations and polyhydramnios), prolonged labor, chorioamnionitis, use of tocolytics, and general anesthesia with halogenated compounds. Despite the myriad causes, uterine atony is a diagnosis of exclusion. Physical examination to rule out obstetric trauma and retained products of conception must be done before reaching the diagnosis. On examination, the uterus is palpable as a soft, boggy mass.

After other causes have been excluded, therapy to augment myometrial contraction should be instituted to prevent further hemorrhage. Two-handed uterine massage may stimulate uterine contraction. One hand exerts pressure transabdominally while the other supports the uterus via the introitus. Uterotonics in conjunction with massage usually provide enough stimuli to control bleeding. Blood should be typed, crossmatched, and available for resuscitation should these measures fail.

Maternal Birth Trauma. Maternal birth trauma is the second most common cause of postpartum hemorrhage, accounting for 20% of the cases. Uncontrolled delivery, macrosomia, and malpresentation all may result in maternal birth-related trauma. Although genitourinary structures are most commonly involved, any part of the birth canal—associated anatomy may be injured, with resultant postpartum hemorrhage. Tears and lacerations might involve the perineum, rectum, cervix, vagina, vulva, and urethra. Blood vessels beneath the vulvar or vaginal epithelium can also be injured without frank hemorrhage, resulting in the formation of large, contained hematomas. These hematomas may go unrecognized for hours, gradually enlarging and eventually resulting in hemorrhagic shock. This type of hemorrhage should be suspected whenever there is evidence of ongoing blood loss and no identifiable obstetric site of bleeding (a firm uterus and negative examination for lacerations). Delayed postpartum hemorrhage at these sites can also occur and is often a diagnostic challenge.

Tears. Vaginal tears, especially posteriorly over the ischial spines, should be diagnosed early by postpartum exploration rather than hours later when the mother is hemorrhaging. The vulva, including periurethral structures, should be examined. Although minor tears may be left, any laceration involving subcutaneous tissue should be repaired with absorbable suture.

The most common sites of tears are the vaginal, perineal, and rectal structures. Tears are classified as first, second, third, and fourth degree. First-degree tears involve the perineal skin and vaginal mucous membranes without involvement of the underlying fascia and muscle. Second-degree lacerations extend through the skin into the fascia and muscles of the perineal body but not into the rectal sphincter. Third-degree tears involve the skin, mucous membranes, perineal body, and anal sphincter. Fourth-degree tear involvement extends through all layers, including the rectal mucosa. These lacerations are also associated with tears in the region of the urethra.

The repair of these tears and the repair of episiotomies are virtually identical. Commonly, repair of the episiotomy is delayed until the placenta is delivered, which allows an uninterrupted approach to potentially complicated repairs. The goal of these repairs is to restore anatomy and provide hemostasis with a minimum of suturing. Third-degree and fourth-degree tears should be repaired by the obstetrician in an operating room.

Retained Products of Conception. Approximately 10% of postpartum hemorrhage cases are due to retained placental tissue. Normally, the plane of cleavage between the zona basalis and the zona spongiosa results in clean separation of the placenta from the uterus. When this occurs, the placental tissue delivers as a single unit, without evidence of fragmentation. Occasionally, accessory placental tissue exists as succenturiate placenta, but this also should cleave normally and deliver spontaneously.

Any placental defect or evidence of accessory placental tissue may signify a retained cotyledon. Retained fragments prevent myometrial constriction and result in hemorrhage. Inappropriate traction on the placenta during stage 3 of labor can result in tears with retained products of conception, which may cause immediate and delayed postpartum hemorrhage. Ultrasonography may be utilized in the diagnosis of retained placenta, with an empty or fluid-filled uterus providing a high negative predictive value and an expanded endometrium or solid echogenic masses within the uterus providing evidence of retention.

Treatment requires removal of the remnant placental tissue. Digital uterine exploration with blunt dissection of the fragments from the myometrium allows myometrial contraction. Normal placental tissue cleaves away easily, allowing removal. Abnormally adherent tissue is not freed by this mechanism.

Placenta Accreta, Increta, and Percreta. Placenta accreta, increta, and percreta describe various degrees of abnormal placental attachment to the uterus. Placental villi may invade the myometrium at the site of implantation, firmly rooting the placenta and obliterating the normal cleavage plane. Thus, abnormal attachment results in retained products of conception and postpartum hemorrhage. When the placenta adheres to the myometrium without the intervening decidua basalis, it is termed placenta accreta. In placenta increta, the villi extend into the myometrium. In placenta percreta, the placenta penetrates the full thickness of the myometrium.

The incidence of these placental disorders is 1 in 2000 to 7000 deliveries. Placenta accreta occurs in 80% of these cases. Associated risk factors include multigravidity, prior cesarean sections, placenta previa, previous curettage, and uterine infections.

Management

Uterine Exploration and Placental Removal. In the face of ongoing hemorrhage and retained products of conception, attempts to remove the placenta manually are indicated. The procedure entails risk of infection, perforation, and increased hemorrhage but may be the most expeditious way to control bleeding. Before beginning, the patient should be on a monitor, good vascular access should be established, and blood products should be available.

The umbilical cord is traced through the cervical os to the placenta, allowing the identification of a placental margin. The placental membranes are digitally perforated, and the placenta is gradually divided from the myometrium. The palmar surface of the hand should be directed toward the placenta, taking care to avoid uterine perforation. After placental removal, the uterus should be explored for retained cotyledons. Removal of any further fragments still present requires curettage of the uterine cavity by an obstetrician. Placenta accreta, percreta, and increta may be diagnosed in this way because these are not digitally dissectible.
Once emptied, the uterus can be stimulated to contract. Uterine massage, oxytocin, and prostaglandins all may be used.

**Uterine Packing.** Uterine packing to decrease postpartum hemorrhage was widely used previously but now is uncommon. For the emergency physician, this technique may be used to create tamponade, preventing further blood loss. The procedure has limited morbidity and is straightforward. The physician introduces 15 to 20 yards of 4-inch gauze with a ring forceps and packs it into the uterus using a layering technique. A special “uterine packer” is available to help direct gauze high into the uterus but is not necessary.

Opponents of packing point out that an atonic uterus may accommodate a large volume of packing and blood without effective tamponade. Packing may also increase the risk of postpartum infection even when prophylactic antibiotics are given. As with all uterine manipulation and instrumentation, some risk of perforation also exists. Because dilation and curettage and hysterecomy sometimes are not available to the emergency physician, the importance of uterine packing as an option is increased. This approach is a temporizing measure.93

**Pelvic Vessel Embolization.** Pelvic bleeding postpartum can be difficult to control. Hysterectomy as a solution results in infertility and brings with it all the complications of general anesthesia and major surgery. Radiographic embolization of the bleeding vessels by an interventional radiologist is another option. The procedure does not require an anesthesiologist, operating room, or obstetrician and may, in fact, be more available on an emergent basis. The success rate of embolization is estimated to be 90%.94

A catheter is placed in the aorta and fluoroscopically guided to the bleeding sites that are imaged by radiopaque dye. The vessels are embolized with absorbable gelatin sponges placed via the catheter. Common sites of bleeding include the uterine artery, pudendal artery, and hypogastric artery. Because only the smallest involved branches are embolized and recanalization usually occurs, future reproductive capability is generally preserved.95

**Uterotonic Agents.** The use of uterotonic agents, although commonly applied upon delivery of the placenta, also has special application in the case of postpartum hemorrhage. Uterotonic agents, such as oxytocin, ergot alkaloids, and prostaglandins, control bleeding by inducing myometrial contraction. Oxytocin is considered to be first-line treatment, given either intramuscularly or intravenously. Ergot alkaloids, such as methergine and ergotamine, may induce hypertension and are therefore contraindicated in patients with pre eclampsia or other comorbid conditions. Finally, prostaglandins may also be used, although the F class is contraindicated in asthma.96

**Hysterectomy.** Most postpartum hemorrhages are controllable with uterotonic agents and massage or uterine exploration for products of conception. Rarely, hemorrhage continues despite the interventions outlined. Life-threatening obstetric bleeding may require emergency hysterectomy. The desire to preserve the patient’s reproductive capabilities must not be given priority if her life is in jeopardy.96

A speedy search for the refractory cause of hemorrhage is warranted because coagulopathies may complicate obstetric hemorrhage. Disseminated intravascular coagulation (DIC) can occur as a consequence of placental abruption, eclampsia, amniotic fluid embolism, postpartum infections, and dilution of clotting factors caused by aggressive volume resuscitation. Also, retained products of conception and dead fetal tissue contain excess thromboplastin, which can initiate DIC. All women with severe postpartum hemorrhage should be evaluated for DIC. As with DIC from nonobstetric causes, clinical signs of bleeding are associated with hypofibrinogenemia, thrombocytopenia, and elevated levels of fibrin split products and D-dimer.97

Appropriate management entails hemodynamic support as well as correction of coagulopathies. In fact, recent investigations have reported the successful use of recombinant factor VIIa for severe cases of postpartum hemorrhage.98

**Uterine Inversion**

Uterine inversion is an uncommon but serious complication of delivery that occurs during stage 4 of labor. The resultant postpartum hemorrhage can be severe and life-threatening, accounting for a maternal mortality rate of up to 15%. Uterine inversion is relatively rare, complicating 1 in 2000 deliveries.99

It is classified by duration as well as degree of inversion. Risk factors include forceful traction on the umbilical cord (especially in conjunction with a fundal placenta), placenta accreta, maternal congenital abnormalities of the uterus, fundal pressure during delivery, use of magnesium sulfate in the antepartum period, and primiparity.99,100

**Clinical Features.** Clinically, the patient notes the sudden onset of severe abdominal pain. Abdominal examination reveals tenderness and an absence of the uterine corpus, which is potentially visualized at the cervical os or bulging from the introitus. Profuse bleeding leading to hemodynamic instability can also occur. Ultrasound may assist in making the diagnosis. Once uterine inversion is identified, the appropriate mobilization of resources should begin simultaneously with efforts to reestablish the correct anatomic position of the uterus.

**Management.** The highest likelihood for successful repositioning of the inverted uterus is immediately after inversion occurs. If the placenta is still adherent, it should not be removed until after repositioning. Removing the placenta while the uterus is inverted is associated with excessive blood loss. The initial attempt to reposition the uterus should be to push the fundus upward via the introitus. Digital pressure should be directed toward the mother’s umbilicus along the long axis of the uterus. Contraction of the cervical uterine segments can create a muscular ring, preventing repositioning. Therefore, all uterotonics agents should be withheld immediately upon diagnosis of uterine inversion.

If initial attempts fail and a cervical ring develops, pharmacologic attempts to relax the uterus are indicated. Sedation and tocolytics can be used to facilitate uterine replacement. Terbutaline and magnesium sulfate have been used successfully to relax cervical rings. When the uterus has been repositioned, the muscle relaxants should be halted, and oxytocin and prostaglandin therapy should be initiated. Firm manual pressure via the introitus should be maintained until uterine contraction begins, the cervical ring contracts, and the uterus can no longer invert.

If all these measures fail and obstetric/anesthesia backup becomes available, halogenated anesthetics may be used to induce relaxation of the cervical rings with or without an attempt at surgical repair.99

**Uterine Rupture**

Criticism of the high rate of cesarean delivery in the United States has led to an advocacy of vaginal birth after cesarean (VBAC). Prior cesarean section is no longer an automatic indication for repeat cesarean delivery. The high success rate and relative safety of VBAC are countered partly by the risk of uterine rupture. Dehiscence of a surgical scar occurs in 0.6% of VBAC deliveries.101 As more women have VBACs, emergency physicians can expect to encounter uterine rupture.
Clinical Features. Uterine rupture is an unpredictable event occurring late in pregnancy or as stage 1 of labor transitions to the active phase. It is defined as a full-thickness uterine wall perforation. The severity of rupture ranges from simple scar dehiscence to complete fetal extrusion. It may be spontaneous, but it is most often linked with previous uterine surgery.

This diagnosis should be entertained when appropriate because significant fetal mortality is associated with the event. As the degree of fetal expulsion through the rupture increases, the fetal mortality rate increases as well. Minimal fetal extrusion results in a perinatal mortality rate of less than 1%, whereas complete extrusion results in a 10 to 20% mortality rate. Maternal death is rare, but significant hemorrhage is common, complicating one third of cases. Maternal genital injury may also occur in association with uterine rupture.

Diagnosis and Severity. The diagnosis of uterine rupture is sometimes difficult because pain is not always present. Risk for uterine rupture with VBAC generally cannot be predicted based on maternal characteristics except that women with a prior classic, or T-shaped, incision and women who have had more than three cesarean sections are at increased risk. Intrapartum vaginal bleeding may signal the problem, but its absence by no means precludes rupture. Prolonged fetal heart rate deceleration, indicating fetal distress, is the most reliable sign of fetal extrusion. Emergency ultrasonography may reveal a protruding amniotic sac, hemoperitoneum, and/or the site of myometrial rupture; however, good sensitivity data are lacking.

Management. If uterine rupture is suspected, delivery should be hastened to limit fetal hypoxia. Emergency cesarean section is the best method to speed delivery and repair the injury. The American College of Obstetricians and Gynecologists guidelines for uterine rupture identify a 30-minute window of opportunity that maximizes fetal outcome. At surgery, the maternal condition dictates whether uterine repair or hysterectomy is indicated. In the absence of opportunity for emergency laparotomy, appropriate interventions remain speculative. Uterotonic agents (especially ergonovine) may enlarge the rupture and are contraindicated.

Amniotic Fluid Embolism

Amniotic fluid embolism is a rare and catastrophic complication of labor and delivery. The incidence rate is 6.0 and 14.8 per 100,000 in primigravid and multiparous deliveries, respectively. Although the mechanism is not well understood, it is thought to involve the spread of amniotic fluid through the maternal vasculature, activating either a procoagulant or anti-phylactic cascade. Uterine trauma at or around the time of delivery, amnioceintesis, and miscarriage may also result in amniotic fluid embolism. The diagnosis is usually clinically evident with the sudden onset of dyspnea, hypoxia, altered mental status, seizure, or hemodynamic collapse. DIC frequently follows and maternal mortality is high. In more than half of amniotic fluid embolism patients, postpartum bleeding due to coagulopathy occurs. Central hemodynamic monitoring, vasopressors/inotropes, and DIC management may be needed.

Postpartum Cardiomyopathy

Clinical Features. Symptom onset varies, as does the severity of the cardiomyopathy. Onset is usually days to weeks after delivery, and symptoms range from mild fatigue to acute pulmonary edema. PPCM is often unrecognized in its milder form, leading to the consensus that the condition may be more prevalent than reported. Dyspnea on exertion, orthopnea, and fatigue may be easily misinterpreted as normal in a mildly anemic woman who is breast-feeding a new infant at home. The clinician should not dismiss these symptoms because congestive heart failure and dysrhythmias may ensue.

Management. Treatment with diuretics, vasodilators, and oxygen relieves the symptoms in many cases. Angiotensin-converting enzyme inhibitors are contraindicated if PPCM occurs during the following 6 months. Others have residual left ventricular dysfunction and a cardiac mortality of 85% during the next 5 years. The presence of cardiomyopathy after one pregnancy does not predict recurrence during subsequent pregnancies. Most obstetricians recommend against future pregnancies, however, believing that there is some residual cardiac function impairment. If such a pregnancy cannot be avoided, it should be considered high risk and followed closely.

Postpartum Depression

Clinical Features. Although likely underdiagnosed, it is estimated that postpartum depression affects 10 to 15% of mothers. Although in many cases it is self-limited, the condition has been recognized as having important consequences for the mother, infant, and family. Risk factors for postpartum depression include previously diagnosed depression and neuroticism, inadequate treatment, and history of depression in a first-degree relative.
spousal support, adverse socioeconomic factors, recent life stressors, and emergency delivery. Clinical Features. Postpartum depression patients present with symptoms not unlike those of other major depressive disorders. These symptoms include depressed mood, anhedonia, loss of appetite, insomnia, fatigue, decreased concentration, feelings of guilt and worthlessness, and suicidal ideation. Most women with postpartum depression do not have vegetative signs or symptoms. Symptoms peak at 10 to 12 weeks postpartum, although some cases are diagnosed up to 1 year postpartum. When unrecognized, these women are at high risk for suicide and may come to the ED with overdoses or other manifestations of a suicidal attempt.

Management. Early identification and referral are the key components of therapy. Dismissal of postpartum fatigue as normal, without considering the diagnosis of postpartum depression, can be disastrous. Not only does this condition contribute to marital discord, maternal risk for suicide, and even infanticide, but also studies have shown that children of depressed mothers have an increased incidence of delayed cognitive, psychological, neurologic, and motor development. Therefore, sensitivity to the possibility of postpartum depression is crucial to successful treatment. The disposition of inpatient psychiatric care with suicide precautions may be required, as deemed appropriate.

KEY CONCEPTS
- ED deliveries should be considered high risk. Antepartum hemorrhage, PROM, eclampsia, premature labor, precipitous delivery, malpresentation, and umbilical cord emergencies are all overrepresented in emergency deliveries.
- Women in labor who present to the ED are generally best cared for in the obstetric suite. Women with the urge to push or with the head of the infant crowning are at imminent risk of delivery, which should take place in the ED. The transfer of a woman with an impending high-risk delivery to a perinatal center must be tempered by clinical and medicolegal judgment.
- Most ED deliveries require only basic equipment to cut and clamp the umbilical cord and to dry and suction the infant. However, the ED should have the equipment and staff available to care for a newborn requiring further resuscitation.
- Maternal complications of labor and delivery include obstetric trauma, postpartum hemorrhage, uterine inversion and rupture, amniotic fluid embolism, coagulation disorders, and infections. Many of these problems can initially be managed nonsurgically in the ED.
- Deliveries complicated by dystocia, malpresentation, or multiple gestations are life-threatening emergencies. The clinician must develop strategies to treat each of these potential complications of delivery.

There are no diseases of the aged, but simply diseases among the aged.

Leonard Larson, 1960

**PERSPECTIVE**

The population of the United States is becoming more elderly, with the proportion of people older than age 65 years increasing at twice the rate of younger people. In 2000, 12.4% of the population was older than age 65 years, and by 2045 one in five people may be older than that age.\(^1\) With the first baby boomer turning 62 years old in January 2008, estimates are that 365 people per hour will reach this milestone during the next decade, and the fastest growing subset of the U.S. population is people age 85 years or older. This group is also the fastest growing population seen in the emergency department (ED). Approximately 35% of total health care dollars are spent on patients older than age 65 years.\(^2\)

These changing demographics affect the practice of emergency medicine. Elders account for 6.4 million of the 110 million ED visits; this number reflects a 34% increase in ED visits by this age group from 1993 to 2003.\(^3\) Nearly half of these patients are admitted. This group accounts for nearly 43% of all ED admissions and 47% of all critical care admissions.\(^4\) Because the number of ED visits for the elderly is expected to nearly double by 2013, the health care impact of this age group will be enormous. In general, elderly patients presenting to the ED are more likely to have an emergent condition than younger patients and spend a longer time being evaluated in the ED.\(^5\)

**PRINCIPLES OF DISEASE**

**Physiologic Changes of Aging**

Physiologic changes of aging affect virtually every organ system and have many effects on the health and functional status of elders (Table 180-1). Heart disease is the leading cause of hospitalization and death.\(^2\) Increased peripheral vascular resistance with aging leads to an increased risk of hypertension. Decreased inotropic and chronotropic cardiac functioning compromises the patient’s ability to respond to physiologic stressors. Atherosclerosis is common and contributes not only to the rate of heart disease but also to the risk of vascular conditions (e.g., stroke, mesenteric ischemia, peripheral vascular disease, aortic dissection, and abdominal aortic aneurysm).

Elders are at higher risk for infections due to decreases in antibody titers. Prostate disease and also incomplete bladder emptying in women with pelvic floor abnormalities predispose to urinary tract infections. Microaspiration increases the risk of pneumonia, and fragile, aging skin prone to injury and breakdown increases the risk of infections of the skin and soft tissues. Immunosenescence of cell-mediated immunity predisposes patients to reactivation of latent diseases (e.g., tuberculosis) and may be associated with increased susceptibility to neoplasms. Cancer is the second most common cause of hospitalization and death in older patients.\(^2\)

Fractures are the fifth leading cause of hospitalization, reflecting the high rate of osteoporosis, particularly in women. Arthritis is the most prevalent outpatient disease in elders because of the wear on the cartilaginous joints, particularly of the knees, hips, and hands.\(^2\) Arthritis greatly affects quality of life, and these patients report fair or poor health approximately three times more often than patients without arthritis.\(^6\)

Although the physiology of aging often affects a patient’s functional status, laboratory values are usually within the normal range. Abnormal laboratory values in elders should be evaluated as abnormal findings and should not be attributed to “normal effects of aging.”

**Pharmacologic Considerations**

Polypharmacy, drug interactions, and misuse and abuse of medications in elders are crucial health care issues. Elders currently consume more than 30% of the prescription drugs in the United States, and this figure is projected to increase to 50% by 2020. More than 40% of elders use 5 or more drugs weekly, and more than 10% use 10 or more.\(^7,8\)

Although multiple medications may be necessary to treat the medical problems that occur with aging, significant adverse health effects may result. Underlying medical problems, multiple physicians, changing pharmacokinetics of aging, and treating side effects of one medication with another drug are all contributory. Twelve to 30% of admitted elders have adverse drug reactions or interactions as a primary or major contributing factor to their admission, and 25% of these drug reactions or interactions are serious or life-threatening.\(^9\)

Pharmacokinetics may change with age. Altered gastrointestinal motility and blood flow, decreased lean body mass, increased proportion of adipose tissue, decreased creatinine clearance, and decreased hepatic blood flow all may alter the absorption, distribution, and clearance of medications. Despite these changes, the bioavailability of most medications is not

</table>

significantly altered in elders. Medication interactions and side effects pose significant problems, however, particularly because so many elders take multiple medications. Emergency physicians unwittingly may contribute to this problem by adding a new medication at discharge that may have an adverse drug interaction with a patient’s preexisting medications. In addition, the altered pharmacokinetics in elders necessitates caution when medications are administered in the ED, particularly sedative-hypnotics and narcotics. A rule of thumb is “start low and go slow.”

Several medications frequently used in the outpatient elder population are “potentially inappropriate medications.” This
list includes, but is not limited to, narcotic analgesics, nonsteroidal anti-inflammatory agents, sedative-hypnotics, muscle relaxants, and antihistamines. These agents are generally not recommended for use in this patient population and should be used sparingly.

The medications most often implicated in adverse reactions in elders in the ambulatory setting are cardiovascular medications, followed by diuretics, nonopioid analgesics, hypoglycemics, and anticoagulants. Caution should be used when prescribing any of these classes that can contribute to morbidity and mortality in this group.

Narcotics and sedative-hypnotic agents can decrease cognition and increase the risk of falls and accidents. Diuretics may cause dehydration or electrolyte imbalance. Nonsteroidal anti-inflammatory drugs (NSAIDs) may have serious and potentially lethal side effects. The toxicity of NSAIDs includes azotemia, worsened hypertension, and congestive heart failure as a result of sodium retention. Gastrointestinal toxicity ranges from bleeding to perforation. The data support using extreme caution when prescribing NSAIDs. These complications can be seen in patients taking widely available over-the-counter formulations of these drugs. There is a significant increase in cardiovascular risk with the use of COX-2 inhibitors.

Due to these concerns, pain management is difficult. Although a “first, do no harm” philosophy is laudable, treatment of pain is one of the most important remedies physicians have to offer. Three major considerations influence the choice of medication for elderly patients. First, chronic pain (e.g., arthritis pain) may require different treatment from an acute painful condition (e.g., wrist fracture). Second, the patient’s underlying medical problems, social situation, and baseline functional status need to be considered. Third, starting with low doses, then titrating upward to effect, is the safest strategy.

Overall, acetaminophen has the highest safety profile in elders and often is the drug of choice for chronic painful conditions (e.g., degenerative joint disease). Although inadvertent excessive dosing can occur, acetaminophen is safe and should be considered first-line management for chronic pain and acute conditions causing mild to moderate pain.

NSAIDs effectively ease pain, but these agents have a ceiling analgesic effect. Increasing the dose increases the risk of side effects without increasing the analgesic benefit. These agents in low doses should be used as second-line agents after acetaminophen in chronic or acute painful conditions.

Narcotics may be necessary for acutely painful conditions and chronic conditions refractory to acetaminophen or NSAIDs. The common side effect of constipation can be problematic, and older patients need to be instructed to exercise regularly, eat high-fiber foods or supplements, and remain well hydrated. Because these agents may decrease cognition, start with low doses and titrate upward as needed.

Psychosocial Issues
The possibility of drug dependence and ethanol abuse should be considered when treating elders. Ethanol dependence is a factor in 14% of elders who present in the ED and is more prevalent than suspected. These patients often present with gastrointestinal complaints or after falls or other trauma. Iatrogenic dependence on prescription drugs, particularly sedative-hypnotics, is also more prevalent than suspected. The routine use of sedative-hypnotics should be avoided and duration limited. Dependence on these drugs may cause decreased cognition, and withdrawal from these agents can be life-threatening.

Psychiatric disease in elders often manifests in atypical fashion. Depression, a common problem, may manifest as agitation, anxiety, and somatic complaints, in addition to the typical depressive symptoms. Depression often follows chronic illness, loss of physical mobility, diminished cognitive function, bereavement from the death of a spouse or long-time friend, and financial pressures, all of which are common features of old age. Social isolation and loss of independence produce a sense of helplessness and hopelessness that may result in suicidal ideation or action. Certain types of depression, such as “late-life delusional depression” and involutional depression, occur exclusively in old age. In addition, depression may be caused by medication side effects or reversible physiologic conditions (e.g., thyroid disease and malnutrition). Elders often respond to pharmacologic treatment of depression but are prone to develop adverse effects from antidepressants; selective serotonin reuptake inhibitors seem to be safer. A phenomenon known as sundown syndrome occurs in elderly demented patients, who become highly agitated and disoriented after dark when visual sensory input is diminished and the environment becomes unfamiliar.

**EVALUATION AND CLINICAL FEATURES**

The evaluation of elders is often difficult. Elders living independently have an average of 3 medical problems, which increases up to 10 for those living in care facilities. Underlying illnesses complicate the evaluation. Many emergency physicians are uncomfortable evaluating elders because a specific complaint is significantly more difficult than managing the same problem in a younger patient. Use of ancillary services can be increased by 50% in elders, most likely because of vague or atypical presentations and complicated medical backgrounds.

**History**
Obtaining a medical history from an elderly patient requires meticulous and painstaking work. Cognitive and physical deficits must be recognized, and physicians often need to be creative and thorough to obtain adequate information.

Cognitive deficits may compromise an elder’s recall and result in an inaccurate medical history. Enlisting family members, consulting with the patient’s primary care physician, and reviewing past medical records may be necessary. Particular attention should be paid to past medical and surgical problems and to the patient’s current medications, including over-the-counter and herbal preparations.

Physical deficits also may impede the history-taking process. Sequelae from previous strokes (e.g., aphasia) are usually obvious. Hearing impairments affect communication and can lead to dangerous misunderstandings. Elders tend to lose high-frequency hearing earlier than other ranges, so physicians should lower the pitch of their voice and speak loudly while ensuring the patient’s privacy. Hearing loss can be embarrassing for the patient; thus, the physician should address the issue with sensitivity to allow for adequate communication while maintaining the patient’s dignity.

**Physical Examination**
Due to the physiologic changes that occur with aging, the physical examination may be misleadingly benign in an elder, despite the presence of a potentially lethal illness. In addition, medications may alter the response of elders to physiologic stressors. Antihypertensives, particularly beta-blockers, may alter the patient’s ability to mount tachycardia in response to hypovolemia or sepsis or may predispose the patient to hypotension.
Differential INCIDENCE of nausea, vomiting, confusion, and weakness.22-24 The prognosis of these patients is generally obtained for these patients than for their younger counterparts who present with similar complaints.3 This increased use of resources is appropriate because the accuracy and timeliness of diagnosis are critical in elders, who suffer greater morbidity and mortality with delays in definitive treatment.

■ DIAGNOSTIC STRATEGIES

Because of the difficulty in obtaining accurate histories and the often poor sensitivity of physical findings in elders with significant underlying disease, more diagnostic tests are generally obtained for these patients than for their younger counterparts who present with similar complaints.3 This increased use of resources is appropriate because the accuracy and timeliness of diagnosis are critical in elders, who suffer greater morbidity and mortality with delays in definitive treatment.

■ SPECIFIC DISORDERS

Myocardial Infarction

The incidence of atypical presentation of acute myocardial infarction (AMI) increases with age.21,22 In patients older than 85 years, atypical presentation of myocardial infarction may be anticipated, and a lack of chest pain may be the rule. Only 2 to 6% of elders with AMI, however, have an asymptomatic presentation.21 A painless myocardial infarction is more common with increasing age and occurs more often in women than men.23-24 Sudden onset of dyspnea may be the only presenting complaint in elders with myocardial infarction. Other presenting complaints include syncope, flulike symptoms, nausea, vomiting, confusion, and weakness.22-24 The prognosis for AMI in elders who present atypically is the same as that for elders who present typically; atypical presentations are not more benign.

Infections

Elders are more prone to infectious diseases than are younger patients, with greater morbidity and higher mortality from these diseases. Common infections occur regularly, but aging causes this population to be more susceptible to unusual organisms. Although immunosenescence is a contributory factor, predisposing illnesses and institutionalization are more significant causes of this increased risk. Hospitalization increases the risk of nosocomial infection. Instrumentation and catheterization are also significant risk factors for acquiring infectious diseases.

Evaluating infections may be difficult because 48% of elders with proven bacterial infections do not have a fever at presentation.20 In addition, the sensitivity of an elevated white blood cell count and bandemia is poor—approximately 44 and 32%, respectively.19 Several infections, particularly pneumonia, urinary tract infections, and sepsis, occur more often in elders. Pneumonia is one of the 10 leading causes of hospitalization and death.2 The elderly are more prone due to decreased vital capacity, decreased lung and airway compliance, less ventilatory drive, and poorer ciliary function. Combined with decreased cough response and increased esophageal reflux with microaspiration, pneumonia is the leading cause of hospitalization due to infection in the elderly. Pneumococcus is still a common cause, but gram-negative organisms are also common, as are mixed infections. Reactivation of tuberculosis also must be considered in this age group.

Urinary tract infections are common in elders. The incidence of bacteriuria is 20% in men older than age 70 and 20% in women ages 65 to 70, increasing to 23 to 50%, respectively, in men and women older than age 80.25 Laxity of the pelvic floor and urinary incontinence are significant risk factors in women, whereas prostate enlargement is a significant risk factor in men. The incidence of urinary tract infections increases dramatically in patients with chronic indwelling catheters.

Abdominal Pain

Abdominal pain may be the most common presenting complaint to evaluate in elderly patients. Despite this difficulty, most patients have a specific diagnosis made in the ED. Two thirds of elders with abdominal pain are admitted, and nearly one fifth go directly to the operating room.

The differential diagnosis (Table 180-2) of abdominal pain differs significantly from that of younger patients, particularly in regard to the number of serious and potentially life-threatening causes. The pathology in more than 60% is surgical in nature, a rate nearly double that of younger patients. There is a 10-fold higher risk of mortality compared with younger patients.26

Due to the physiologic changes of aging, even life-threatening causes of abdominal pain may present with few or no alarming findings. Elders may complain of vague abdominal pain despite the occurrence of a catastrophic process. The complication rates of typically benign processes in younger patients are dramatically higher in older patients. With aging, the abdominal musculature decreases, and patients are less able to manifest guarding and rebound. In addition, the omentum shrinks and is less able to contain intra-abdominal processes. Atherosclerotic disease, with its resultant decrease in blood flow, causes increased perforation rates in diseases such as cholecystitis and appendicitis. This increased rate of vascular disease also contributes to higher rates of vascular causes of abdominal pain, such as mesenteric ischemia and leaking or ruptured abdominal aortic aneurysms.27 The high prevalence of gallstones in elders leads to an increased risk of cholecystitis.

Due to the vague presentation and high rate of serious disease, evaluating an elderly patient with abdominal pain often requires an extensive battery of laboratory and radiographic tests.28 Elders with potentially catastrophic intra-
abdominal processes may not present with a fever or an elevated white blood cell count. As a result, ancillary diagnostic ultrasonography, computed tomography, radionuclide studies, and, occasionally, angiography may be important. Since many elders with abdominal pain have a serious disease, consider admission and close observation when symptoms persist and the diagnosis remains unclear. If the patient is not admitted, a prolonged period of ED observation or reevaluation within 12 hours is prudent.

**Major Trauma**

Major trauma in elders (see Chapter 36) is relatively uncommon, constituting 8 to 15% of cases in major trauma databases. Elder trauma patients, however, experience higher mortality and poorer functional recovery for a given trauma score. In any elderly trauma patient, the circumstances leading to the injury need to be determined. For any elderly patient who presents with a fall, the circumstances of the fall should be questioned. Although mechanical falls occur, falls may be due to potentially serious or life-threatening medical causes such as syncope, hypovolemia due to dehydration or bleeding, cardiac or cerebrovascular disease, or medications. Motor vehicle crashes, particularly involving a single vehicle, may result from transient loss of consciousness due to dysrhythmias, syncope, medication side effects, transient ischemic attacks, strokes, or myocardial infarctions. These serious medical problems require simultaneous diagnosis and treatment in the setting of trauma and may be as important as or more important than the traumatic injuries.

The presence of comorbid illness and the limited physiologic reserve in the cardiopulmonary and renal systems often complicate the trauma resuscitation in this age group. More aggressive ventilatory support and early use of invasive hemodynamic monitoring are indicated to guide volume resuscitation. Shock is poorly tolerated in elders because hemodynamic compensation is limited, and end-organ failure occurs earlier.

Certain injuries are more common and severe in elders. A subdural hematoma may occur after relatively trivial head trauma, and chronic subdural hematoma may present as progressive dementia with only subtle neurologic findings. Increasing ankylosis of the spine, osteoarthritis, and decreased bone density as a result of osteoporosis render the geriatric cervical spine more susceptible to fracture. Preexisting pulmonary pathology and a brittle thoracic wall account for the greater severity of pulmonary contusions and the higher incidence of rib fractures and resultant complications (e.g., atelectasis and pneumonia). Skeletal fractures are more common and lacerations of atrophic skin are more difficult to repair and more prone to infection. This thin skin is also prone to decubitus breakdown in patients who are immobile, even for short periods such as during spinal immobilization on a backboard.

**PREVENTIVE CARE**

**Immunizations**

Pneumonia, influenza, accidents, and adverse medical events are among the top seven causes of death in elders. These conditions account for 15% of admissions and are potentially preventable. Annually, 36,000 adults die of complications from influenza and pneumococcal infections, and most of these deaths occur in elders. Immunization would reduce the incidence of clinical and serologic influenza by half in this patient population. The Centers for Disease Control and Prevention (CDC) has a goal of an 80% immunization rate for patients in high-risk groups, including elders. The actual vaccination rate falls significantly below this goal. In patients 65 years old, 66 and 62% were vaccinated for influenza and pneumococcus, respectively, with the lowest rates among multiracial ethnic groups and people of lower socioeconomic means. As a result, the CDC recommends that potential vaccination sites be extended to include walk-in clinics and EDs. Elders who have not been hospitalized or seen their primary care physician in the previous 3 years average at least one visit to an ED, and many are willing to be vaccinated there.

Despite this information, controversy exists regarding vaccination of elders in the ED. Emergency physicians can be reluctant to give vaccinations, citing time constraints and their concern regarding delivering primary care. Considering the low threshold in the ED to administer the tetanus vaccine, it seems feasible that influenza and pneumococcal vaccination programs could be relatively easy and effective in the ED.

**Falls**

In combination with vaccinations, education about accident prevention in the home could have a considerable impact on the overall morbidity and mortality in elders. Falls and adverse medical events are the seventh leading cause of death in elders. A primary care or social service provider more appropriately supplies this instruction. The ED, however, may be an additional resource for providing educational services to elders on a case-by-case basis, particularly in reference to any specific incident that led to the need for emergency care. The leading cause of falls in elders is related to the use of pharmacologic agents, often prescription drugs. Reviewing the patient’s medications, searching for agents that might cause decreased cognition or dehydration, and addressing the need for these agents with the patient and the primary care provider could decrease significantly the risk for falls. In addition, informing the patient’s primary care provider that the patient has fallen may facilitate education by the primary physician.

---

**KEY CONCEPTS**

- Polypharmacy and side effects of prescription and nonprescription drugs often occur in elders and should be considered in their evaluation.
- Physiologic changes that occur with aging make the clinical evaluation of elders difficult. Because of the difficulty in obtaining accurate histories and the often poor sensitivity of physical findings in elders with significant underlying disease, more diagnostic tests are generally obtained for these patients than for their younger counterparts who present with similar complaints.
- The immunosenescence that accompanies aging may blunt the fever response to infection and cause a less elevated white blood cell count.
- Myocardial infarction frequently presents atypically in elders as dyspnea, syncope, weakness, confusion, or abdominal complaints, often in the absence of accompanying chest pain.
- Abdominal pain in elders is often caused by surgical conditions that may require extensive evaluation in the ED, including radiographic studies.
- Elderly trauma patients have a higher morbidity and mortality than their younger counterparts because of exacerbation of underlying medical problems.

*The references for this chapter can be found online by accessing the accompanying Expert Consult website.*
Compared to individuals with an intact immune system, infections in immunocompromised patients are more common, are more severe, progress more rapidly, are more often fatal, and are caused by a wider variety of microorganisms. Many factors, often interrelated, cause patients to become immunocompromised and predispose them to develop infections with potentially pathogenic microorganisms. These include disruption of the body’s protective surfaces such as skin and mucosal barriers (oral and respiratory mucosa and intestinal and genitourinary surfaces); disorders (e.g., lymphoma, asplenism, and myeloma) that directly impair the function of the body’s immune system; drugs and irradiation that suppress or alter immune function; alterations in body substances (hyperglycemia) or solid organ function (kidney and liver failure); as well as malnutrition, aging, and exposure to antimicrobial agents that inhibit the normal protective resident bacterial flora.

The body’s defense mechanisms consist of surface barriers, such as skin, enzymes, and mucus, as well as innate (natural) and acquired (adaptive) responses. Innate responses occur to the same extent regardless of how often the body encounters the infectious agent, whereas acquired responses improve on repeated exposure. Innate immunity is activated immediately upon exposure to an infecting agent, rapidly controlling replication and allowing the requisite 3 to 5 days for the adaptive component to clone sufficient T and B cells to respond more specifically.

Non-Microbe-Specific Immunity

Physical Barriers

The first line of defense against microorganisms consists of physical barriers, including skin, gastrointestinal and respiratory mucosa, and gastric acid. Cutaneous acidity inhibits dermal bacterial growth. In addition, mucous membranes are continually bathed in secretions that contain antimicrobial enzymes, other proteins, and immunoglobulin G (IgG) and secretory IgA.

In the respiratory tract, mucociliary transport and the cough reflex remove particulate matter and microbes, but this mechanism is impaired with smoking and ineffective cough. Mechanical ventilation or tracheostomy introduces large numbers of microbes that often overwhelm natural clearance.

Gastric acid and pancreatic enzymes have antibacterial properties that prevent overgrowth in the upper gastrointestinal tract. Normal peristalsis and mucosal shedding help maintain normal gut flora. Alterations in these factors increase susceptibility to infection. Broad-spectrum antibiotics alter normal flora, permitting overgrowth of pathogens such as Candida species, multiantibiotic-resistant bacteria, and Clostridium difficile.

Acute Phase Response

The metabolic changes that occur during systemic infection and inflammation constitute the acute phase response. The liver manifests a stress response by decreasing albumin synthesis while increasing production of proteins that enhance phagocytosis and assist in complement activation. One of these proteins is C-reactive protein (CRP), sometimes measured clinically as a nonspecific indicator of infection or inflammation. Muscle proteolysis is also part of this response and may result in the weight loss characteristic of chronic inflammatory or infectious states.

Invading microorganisms activate the acute phase response, which is not microbe specific. The response delivers humoral and cellular immune components to sites of inflammation and initiates antibody responses. Cytokines, platelet-activating factor, and hormone-like proteins, including interferons, are secreted from various immune cells and play important roles in mediating this response. Clinically, these cytokines result in migration and adhesion of polymorphonuclear leukocytes and monocytes to sites of bacterial invasion. These cells release granules of substances that vasodilate and increase vascular permeability, leading to edema, warmth, and redness, but also allow both phagocytic cells and humoral components to concentrate at the site of infection.

A family of distinct transmembrane proteins, called toll-like receptors, which mediate recognition of extracellular microbial products such as endotoxin, are vitally important in the innate immune response. They are present on many cell types, including macrophages, neutrophils, dendritic cells, mucosal epithelial cells, and endothelial cells. They recognize pathogen-associated molecular patterns, generate signals that lead to activation of innate immune responses, and help bridge innate and adaptive immune responses.
The reticuloendothelial system, composed of tissue macrophages and their blood-borne counterparts, monocytes, removes particulate matter, including microbes, from the lymph and blood. The tissue component is concentrated in the lymph nodes, spleen, liver, marrow, and lung and has particular affinity for encapsulated bacteria such as pneumococci, meningococci, and *Haemophilus influenzae*. The vital importance of this non-microbe-specific system is revealed by the overwhelming sepsis from encapsulated organisms in patients with asplenia.

**Reticuloendothelial System**

Adaptive (Microbe-Specific) Immunity

Humoral Immunity

Antibodies. Antibodies are produced by B lymphocytes, and each B cell produces a single microbe-specific antibody type. Stimulation by an antigen (or microbe) causes proliferation of this particular B cell so that large quantities of a specific circulating antibody can be produced. Furthermore, B cells are active in presenting antigens to T lymphocytes, which promotes cell-mediated immunity.

Immunoglobulins. IgM is the first immunoglobulin to appear in response to a new antigen. Although it has less affinity at binding antigens than IgG, IgM provides some recognition of antigens and begins B cell proliferation before the subsequent development of IgG. Clinically, IgM is detectable earlier in serum than IgG and serves as a marker for a patient’s early response to acute infection.

Secretory IgA is the predominant immunoglobulin present in gastrointestinal fluids, nasal and oral secretions, tears, and other mucous fluids. IgA inhibits cell adherence of viral, bacterial, and protozoan pathogens and therefore prevents invasion by organisms through the respiratory or gastrointestinal tract.

IgE, which is expressed in high concentration on the surface of mast cells and basophils, is responsible for immediate-type hypersensitivity responses. Mast cells and IgE are important in defense against helminthic pathogens.

IgG, which accounts for 75% of the total immunoglobulin mass, is widely distributed in tissues. It crosses the placenta and provides fetal immunity during the first 6 months of life. Congenital or acquired deficiencies of IgG lead to infection with encapsulated organisms because the predominant subtype (IgG2) has affinity for the dense polysaccharides of bacterial cell capsules, such as those of *Streptococcus pneumoniae* and *H. influenzae*.

Complement. The complement cascade, consisting of a complex interaction of 30 proteins, is another crucial component of humoral response. Complement is important in producing inflammation and leukocytosis and in recruiting leukocytes to sites of infection by production of chemotactic factors. Complement also neutralizes viruses, enhances opsonization of bacteria, and produces bacterial cell wall and membrane lysis.

Both IgG and IgM, when in contact with an antigen, activate the classical pathway, whereas molecules with repeating chemical structures (e.g., bacterial cell walls and capsules) activate the cascade through the alternative pathway. Components of C3, the merging point of the classical and alternative paths, provide opsonization and modulate the response of lymphocytes (cell-mediated immunity). Opsonization is important in defense against infection with *S. pneumoniae*, *Streptococcus pyogenes*, *H. influenzae*, and *Staphylococcus aureus*. The terminal leg of the cascade, C5 through C9, forms the membrane attack complex, which inserts into cell walls and membranes and leads to cell death.

Individuals with inherited complement deficiencies are predisposed to frequent and recurrent infections with *S. pneumoniae*, *H. influenzae*, and especially *Neisseria meningitidis* and *Neisseria gonorrhoeae*. The risk of meningococcal infection is increased several thousandfold and most often develops in people deficient in C3 and in late complement components (C5–C8). Paradoxically, the disease is usually milder with complement deficiency, and mortality is likewise reduced 5- to 10-fold. This suggests that the host response may be, in part, responsible for the severity of disease in normal individuals and is attenuated in complement deficiency. People with meningococcal choriae should be tested for inherited complement deficiencies because they may benefit from immunization.

Acquired deficiencies of complement function may develop in people with rheumatologic diseases, especially systemic lupus erythematosus (SLE). Approximately 40% of patients with SLE have an inhibitor of C5a-derived chemotaxis in their serum that results in enhanced susceptibility to infection.

**Cell-Mediated Immunity**

Cell-mediated immunity (CMI) generally includes immune responses that are mediated by T lymphocytes, natural killer (NK) cells, and mononuclear phagocytes. CMI is vital in the control of infections caused by microbes that survive and replicate intracellularly, including most viruses, and some bacterial (obligate and facultative intracellular types), fungal, and protozoan pathogens.

Only 5% of lymphocytes are in circulating blood. Most mature and are active in the marrow, thymus, spleen, and lymph nodes. The latter two sites expose T cells to circulating antigen from invading microbes. Specialized antigen-presenting cells in the lymphoid system sequester antigen and antigen-antibody complexes and present them to T cells. This process involves internalization and processing of the antigen, followed by formation of peptides that bind to a cell surface molecule called the major histocompatibility complex (MHC). Only with this specific presentation can a T lymphocyte become activated against a particular antigen.

Two major types of T lymphocytes are CD4 (helper cell) and CD8 (suppressor cell), corresponding to type II and type I of MHC, respectively. CD4 lymphocytes provide help for other cells in the immune system, including enhanced B cell antibody production and production of cytokines. CD8 lymphocytes are generally cytotoxic and mediate the eradication of virally infected target cells and certain tumors. A decline in the number of CD4 cells, with predominance of CD8 cells, is responsible for the increased susceptibility to infection in patients with acquired immunodeficiency syndrome (AIDS). Despite the cytotoxicity of CD8 cells, immunity is reduced without adequate numbers of CD4 cells.

Patients with defects in CMI are at increased risk for disseminated infection with intracellular bacteria, such as *Mycobacterium tuberculosis*, *Listeria monocytogenes*, and *Salmonella* species. The deoxyribonucleic acid (DNA) viral infections, such as cytomegalovirus, herpes simplex, and varicella zoster, also affect these patients more severely, as do fungal infections with *Candida*, *Cryptococcus*, *Mycor. Aspergillus*, and *Pneumocystis*. Finally, some protozoa are pathogenic without intact CMI, as infections with *Toxoplasma gondii* demonstrate. Some infections are seen only below a certain CD4 cell count. *Pneumocystis* pneumonia is seen almost exclusively in patients with counts less than 200 cells/mL, whereas almost all patients with
toxoplasmosis or cryptococcal meningitis have counts less than 100 cells/mL.

NK cells, closely related to lymphocytes but neither B nor T cells, are important in the innate immune response and are found in high concentrations in blood and spleen.\(^5\) NK cells recognize infected cells and respond by directly killing these cells, and they secrete cytokines that activate macrophages to destroy phagocytosed microbes. These cells are very important in defense against intracellular microbes, particularly viruses and intracellular bacteria such as *L. monocytogenes*.

**Granulocytic Phagocytes.** Granulocytic phagocytes are the cellular effectors of microbe killing, engulfing them and enzymatically lysing their cell membranes or walls. Two major types are polymorphonuclear leukocytes (also called neutrophils) and macrophages (the tissue version of circulating monocytes). Macrophages have surface receptors that recognize nonvertebrate carbohydrates such as mannose, which form the cell wall of some microorganisms. Hence, they can identify and attack “invaders” rather than “self.”

Two other types of granulocytes, eosinophils and basophils, are less involved in the ingestion of organisms.\(^6\) Eosinophils mediate the destruction of certain parasitic helminths through release of toxic proteins. Normally only 3% of total granulocytes, this cell type can reach 20% during times of high parasite load. Basophils (rare in circulation) and their tissue counterparts, mast cells, have high affinity for IgE. When exposed to antigens, they release granules with histamine, prostaglandins, and leukotrienes, which affect the allergic-inflammatory response with increased vascular permeability, bronchospasm, and vasodilation.\(^3\)

Neutrophils constitute 90% of circulating granulocytes and spend only 6 to 8 hours of their average 4-day life in circulation (the remainder in tissues). Effective antibacterial activity depends on the ability of neutrophils to travel to sites of infection—a process known as chemotaxis. The locomotion of neutrophils along vascular endothelium is facilitated by adherence to cell surface proteins whose production is enhanced in the acute phase response.\(^6\)

One half of all neutrophils that leave the bone marrow circulate in the plasma. The other half become marginated, adhering to endothelium, primarily in the lungs, liver, and spleen. During periods of stress or with endogenous or exogenous catecholamines or corticosteroids, these neutrophils demarginate and enter the circulation. As long as the patient is not neutropenic, demargination causes an increased peripheral neutrophil count composed of mature cells, whereas with infection, an increased proportion of immature (band) forms is typically seen.

Neutrophils (and macrophages in tissue) bind to and ingest bacteria—a process called phagocytosis. This process is enhanced by proteins called opsonins that bind to bacterial surfaces. CRP, one of the acute phase response proteins, fulfills this function for certain bacteria, including *S. pneumoniae*. IgG and complement protein C3b also opsonize bacteria, again illustrating the interdependence of the immune system. Actual killing takes place within granulocytes when cytoplasmic granules enzymatically produce potent oxidants. Granulocytes further control bacterial proliferation at the site of infection by elaborating lactoferrin, which locally binds free iron necessary for bacterial replication.

In addition to phagocytosis, macrophages (located in the spleen, alveoli, liver, and lymph nodes) modulate the immune response by presenting antigens to lymphocytes and releasing cytokines and complement components. Activation of macrophages to ingest bacteria depends on interaction with interferon-γ, a cytokine manufactured by T cells.\(^5\) Thus, the once clear demarcation between cellular and humoral immunity is breaking down as more is understood about the interdependent immune system.

### SPECIFIC IMMUNOCOMPROMISED STATES

#### Solid Organ Transplants

See Chapter 182.

#### Cancer

Patients with cancer frequently have multiple immune defects that predispose them to infection, such as neutropenia and impaired T cell and B cell function, which are induced by cancer chemotherapy or by the disease process. Other factors leading to infection are defects in physical barriers (skin and mucous membranes), including cytotoxic effects of chemotherapy on cells lining the gastrointestinal tract. In addition, splenic dysfunction or splenectomy, use of long-term intravascular catheters, frequent use of complex invasive diagnostic and therapeutic procedures, toxic effects of radiation therapy, and frequent colonization with antimicrobial-resistant pathogens are predisposing factors. Cancer treatments (e.g., allogeneic bone marrow and autologous stem cell transplantation, platelet transfusion, granulocyte colony-stimulating factor, and implanted central venous catheters) increase survival during episodes of profound immunosuppression, allowing patients to receive more intense cytotoxic cancer chemotherapy regimens. This results in long survival of patients with neoplastic diseases that were formerly rapidly fatal. Despite many advances in supportive care, infections continue to result in serious morbidity and mortality. Furthermore, increasing resistance to antimicrobials is occurring among common pathogens, along with the emergence of new opportunistic pathogens. Infection is much more common in patients with acute leukemia and lymphoma (75% of patients) and multiple myeloma (50% of patients) compared to those with solid tumors.\(^7\) Factors predisposing to infection in immunocompromised patients are listed in Box 181-1.

#### Neutropenia

**Principles of Disease.** Neutropenia is defined as a neutrophil count of less than 500 cells/mL, including band forms, or less than 1000 cells/mL and expected to fall to less than 500.\(^18,19\) It usually results from cytotoxic chemotherapy or radiation therapy or the disease process, especially in hematologic malignancies. In addition, cancer chemotherapeutic agents and radiation therapy can cause functional defects in granulocytes. The risk of febrile neutropenia and mortality is higher in the first one or two cycles of multicycle cytotoxic chemotherapy regimens.\(^20\)

The incidence and severity of infection in cancer patients with neutropenia are inversely proportional to the absolute neutrophil count and directly proportional to the duration of neutropenia. Although the incidence begins to rise as the neutrophil count falls below 500 cells/mL, most severe infections and almost all bacteremias occur when the neutrophil count is less than 100 cells/mL.\(^21\) Fever in the neutropenic patient is defined as a single temperature of 38.3°C (101°F) or higher or a temperature of 38.0°C (100.4°F) or higher over 1 or 2 hours.\(^19\) In neutropenic patients, the temperature should be measured orally or tympanically, not rectally. Although fever can be suppressed or lessened by immunosuppressive agents such as corticosteroids and nonsteroidal anti-inflammatory
The Immunocompromised Patient: Factors Predisposing to Infection and the Most Common Pathogens

### Neutropenia

**Bacteria**
- *Escherichia coli*
- *Klebsiella pneumoniae*
- *Pseudomonas aeruginosa*
- *Enterobacter sp.*
- *Serratia sp.*
- *Citrobacter sp.*
- *Proteus sp.*
- *Stenotrophomonas maltophilia*

**Gram-positive cocci**
- *Staphylococcus epidermidis*
- *Staphylococcus aureus*
- *Viridans streptococci*

Less common: *Enterococcus sp.*

**Gram-positive rods**
- *Corynebacterium sp.*

Less common: *Bacillus sp.*

**Fungi**
- *Candida sp.*
- *Aspergillus sp.*

Less common: *Mucor sp.*, *Rhizopus sp.*, *Trichosporon beigelii*, *Fusarium sp.*, *Pseudallescheria boydii*

### Cellular Immune Dysfunction

**Bacteria**
- *Listeria monocytogenes*
- *Salmonella sp.*
- *Mycobacterium tuberculosis*
- *Mycobacterium avium-intracellulare*
- *Legionella sp.*
- *Nocardia sp.*

**Fungi**
- *Cryptococcus neoformans*
- *Histoplasma capsulatum*
- *Coccidioides immitis*

### Complement Deficiency

**Bacteria**
- *S. pneumoniae*
- *H. influenzae*
- *N. meningitidis*
- *C. meningosepticum*
- *Bordetella holmesii*

**Parasites**
- *Babesia sp.*

### Humoral Immune Dysfunction (Antibody Deficiency)

**Bacteria**
- *Streptococcus pneumoniae*
- *Haemophilus influenzae*
- *Neisseria meningitidis*
- *S. aureus*

**Fungi**
- *Aspergillus sp.*

Less common: *Rhizopus sp.*, *Trichosporon beigelii*, *Fusarium sp.*, *Pseudallescheria boydii*

**Parasites**
- *Toxoplasma gondii*
- *Cryptosporidium sp.*
- *Strongyloides stercoralis*

### Splenectomy/Functional Asplenia

**Bacteria**
- *S. pneumoniae*
- *H. influenzae*
- *N. meningitidis*
- *C. meningosepticum*
- *Bordetella holmesii*

**Parasites**
- *Babesia sp.*

### Complement Deficiency

**Bacteria**
- *S. pneumoniae*
- *H. influenzae*

**Fungi**
- *Candida sp.*
- *Aspergillus sp.*
- *Pneumocystis jirovecii* (formerly *carinii*)

**Viruses**
- *Herpes simplex*
- *Varicella zoster*
- *Cytomegalovirus*
- *Epstein-Barr*

Less common: *Measles, adenovirus*

**Parasites**
- *Toxoplasma gondii*
- *Cryptosporidium sp.*
- *Strongyloides stercoralis*

During the past 25 years, infection with gram-positive organisms (e.g., *coagulase-negative staphylococci, S. aureus*, viridans streptococci, and *Enterococcus species*) has increased and this is now the leading cause of bacterial infection (50–70% at some centers) in febrile neutropenic cancer patients in the United States, Canada, and Western Europe. Gram-negative organisms still predominate in developing countries. With the exception of viridans streptococci, most of these gram-positive organisms do not produce immediately life-threatening infections compared with the rapid lethality of many gram-negative infections. Life-threatening bloodstream infections caused by viridans streptococci (especially *Streptococcus mitis*) are common in many cancer centers and often respond poorly to penicillins and cephalosporins. Risk factors for serious viridans streptococcal infections include aggressive cytoreduction therapy for acute leukemia or allogeneic bone marrow transplantation (especially after high-dose cytosine arabinoside treatment), profound neutropenia, and severe oral mucositis. Other factors...
include prophylactic use of trimethoprim-sulfamethoxazole (TMP-SMX) or fluoroquinolones, use of antacids or H2 receptor antagonists, and childhood.26

Aspergillus and Candida species are the most common fungi producing infection in cancer patients with fever and neutropenia.23,29 They are most likely to develop in neutropenic patients treated with broad-spectrum antimicrobials and whose fever has persisted for more than 7 days. Aspergillus species usually produce necrotizing infections in the lung or sinuses. Pulmonary aspergillosis often presents with pleuritic pain, hemoptysis, and localized wheezing. The chest radiograph demonstrates pleural effusion or focal infiltrates. Computed tomography (CT) is more sensitive in detecting pulmonary infiltrates compatible with aspergillosis, and it may demonstrate a distinct halo of low attenuation surrounding a pulmonary infiltrate. This pattern is highly suggestive of invasive aspergillosis, although mucormycosis and other disorders may mimic the halo. Invasive aspergillosis originating in the paranasal sinuses may extend to the surrounding bone and brain. Often, an initial red-purple lesion on the nasal turbinates or palate turns pale and then black as vascular invasion produces infarction of the mucosa and bone. The black eschar on the nose or palate is easily misdiagnosed as dried blood. Patients presenting with head or facial pain or swelling, or proptosis, should be rapidly evaluated for invasive aspergillosis and mucormycosis. Candida species produce infections of the skin, oral cavity, and esophagus as well as fungemia. The sudden onset of generalized rash consisting of pinkish-purple, nontender subcutaneous nodules is characteristic of candidemia.

Less common fungi producing infection in these patients include Mucor and Rhizopus species (necrotizing pneumonia and sinusitis), Trichosporon species (pneumonia and fungemia), and Pseudallescheria boydii (soft tissue infection). Other than Candida species, these fungi are rarely found in blood cultures. Specific diagnosis requires biopsy.

Clinical Features. Certain clinical findings are characteristic for specific pathogens (Table 181-1). Noninfectious causes of fever also need to be considered, such as drug toxicity, drug allergy, transfusion reactions, and pulmonary emboli.17 Fever is frequently the only sign of infection because these patients are unable to mount a full inflammatory response at a site of infection.21 Usual symptoms and signs of infection may not be present, especially when the neutrophil count is less than 100 cells/mL. When pneumonia develops, purulent sputum may be absent, and the initial chest radiograph may not show an infiltrate. Pyuria may be absent in the presence of urinary tract infection. Areas of cellulitis may have diminished or absent induration and redness and no purulent drainage. Tenderness may be the only finding in perineal and anal infections. The neutropenic patient with a documented infectious cause of fever may be difficult to distinguish from the patient with fever not caused by infection. The performance of a procedure before the onset of fever, the presence of chills, “toxic appearance,” and lack of localized findings do not help determine whether the patient is bacteremic.30 Only 20% of febrile neutropenic patients have a clinical focus of infection identified at presentation, and only 30% of patients have positive blood cultures.

Mucositis involving the mouth and other mucous membranes is a painful and debilitating condition that commonly occurs in cancer patients receiving intense chemotherapy. It is a frequent prelude to viridans streptococcal bacteremia, which can produce sudden onset of acute respiratory distress syndrome, a toxic shock–like syndrome, rash, and pneumonia.

Diagnostic Strategies. The emergency evaluation of the cancer patient with fever and neutropenia should include a meticulous search for subtle symptoms and signs of inflammation at common sites: oral cavity and pharynx, lower esophagus, lung, skin, perineum including anus, bone marrow aspiration sites, vascular catheter sites, and tissue around the nails.21 In nearly two thirds of patients, the initial evaluation does not identify a focus of infection.22 Two sets of blood cultures should be obtained. If the patient has a central venous catheter, cultures of blood should be obtained from one lumen of a multilumen catheter and from at least one peripheral site. Specimens for culture should also be obtained from any site of inflammation, including inflamed or draining catheter exit sites. Patients with severe mucositis should have herpes simplex cultures performed if not on antiherpes prophylaxis, and they should have a smear for Candida pseudohyphae. Complete blood count, electrolytes, transaminases, blood urea nitrogen, and creatinine should be obtained to plan management and to monitor the occurrence of drug toxicity.

Urine culture should be obtained if symptoms or signs of a urinary tract infection are present, if a urinary catheter is in place, or if the urinalysis is abnormal. Examination of the cerebrospinal fluid is not recommended as a routine procedure unless subtle symptoms or signs of meningitis are present.

A chest radiograph should be obtained even when symptoms or signs of pneumonia are absent. If the chest radiograph is negative or inconclusive but there is still suspicion for pneumonia, high-resolution CT or thin-section multislice CT scanning of the chest without contrast should be obtained because

pneumonia is often detected by chest CT in febrile neutropenic patients with normal findings on chest radiograph. CT evaluation of the sinuses should be performed if facial pain or swelling is present. In patients with abdominal pain and tenderness, CT scanning of the abdomen is useful for diagnosing neutropenic enterocolitis (“typhlitis”), a necrotizing infection of the bowel wall that usually affects the cecum. This is more commonly seen in acute leukemia and is not generally treated surgically. Ultrasonography over a subcutaneous tunneled catheter tract and its vein of insertion may reveal the presence of an abscess or infected thrombus.

In patients with diarrhea, stool testing for *C. difficile* toxin as well as culture for routine bacterial pathogens should be obtained. *C. difficile* colitis occasionally produces abdominal pain in the absence of diarrhea. *Cryptosporidium parvum*, a protozoan, may cause profuse, watery diarrhea and is detected by acid-fast staining or immunofluorescence testing of stool.

### Management of Febrile Neutropenia

#### Antibiotic Therapy

Broad-spectrum antimicrobial therapy should be initiated promptly in the febrile neutropenic patient if the neutrophil count is less than 500 cells/mL or if the neutrophil count is 500 to 1000 cells/mL and is expected to drop. Moreover, even afebrile neutropenic patients who have symptoms and signs (e.g., abdominal pain and tenderness) compatible with an infection should be treated empirically (Table 181-2).

Use of a single antimicrobial agent is preferred in most patients because there is no conclusive evidence of a benefit from multiple drugs.

*Alternative for herpes simplex:* famciclovir 250 mg three times a day, or valacyclovir 1 g two times a day PO.

†Alternative for herpes zoster: famciclovir 500 mg three times a day, or valacyclovir 1 g three times a day PO q8–12h.
To prevent and treat neutropenia, some agents effective against anaerobes (clindamycin, metronidazole, or erythromycin), are common pathogens at some centers. In addition, ceftazidime is the least active against gram-positive organisms, compared with ceferazone, cefotaxime, or ceftriaxone. Ceftazidime, a broad-spectrum cephalosporin with excellent activity against both gram-positive and gram-negative organisms including *P. aeruginosa*, is now preferred at many centers. The carbapenems imipenem and meropenem provide excellent activity against gram-negative organisms (including *P. aeruginosa*), gram-positive organisms, and anaerobic bacteria. None of the antimalarial agents previously listed is active against vancomycin-resistant *Enterococcus* species or methicillin-resistant staphylococci.

For patients who are allergic to β-lactam antibiotics (e.g., penicillins, cephalosporins, imipenem, and meropenem), coverage of gram-negative bacilli, including *P. aeruginosa*, can be provided by aztreonam. Because aztreonam is not active against gram-positive or anaerobic bacteria, it should be combined with an antifungal such as vancomycin. If anaerobes are suspected (i.e., oral, abdominal, or perianal infection) in the β-lactam allergic patient or in the patient receiving cephalosporin monotherapy, an antianaerobic drug such as clindamycin or metronidazole should be administered. Empirical treatment with intravenous fluoroquinolones is not recommended in the febrile neutropenic cancer patient because of frequent prophylactic use of these agents in the cancer patient, risk for rapid emergence of resistance in gram-negative bacilli, and predisposition to *C. difficile* infection.

When a focus of infection is identified, empirical therapy should cover the most likely pathogens causing infections at the site. For example, patients with pneumonia may need coverage for *Legionella* (fluoroquinolone, azithromycin, doxycycline, or erythromycin), *Pneumocystis* (TMP-SMX), or fungi (amphotericin B) in addition to standard antibacterial coverage. Agents effective against anaerobes (clindamycin, metronidazole, imipenem, meropenem, and piperacillin-tazobactam) should be considered for patients with perianal or oral infection and those with abdominal pain, who may have appendicitis, diverticulitis, or typhilitis (neutropenic enterocolitis). Acyclovir should be considered for patients with ulcerative or vesicular lesions who may have herpes simplex or varicella zoster virus infections. Ganciclovir may be required to treat cytomegalovirus infection, which is rare in febrile neutropenic cancer patients. Foscarnet may be needed for acyclovir-resistant herpes simplex or ganciclovir-resistant cytomegalovirus infections. In patients with severe mucositis and febrile neutropenia, a carbapenem or extended-spectrum penicillin is preferred for empirical treatment rather than a higher-generation cephalosporin because of superior efficacy against viridans streptococci.

Routine empirical use of vancomycin for the febrile neutropenic cancer patient is not recommended because of concern about the development of vancomycin-resistant organisms. Randomized clinical trials show no survival advantage when vancomycin is in the initial therapy for all neutropenic patients, even those with indwelling catheters. Because most infections with gram-positive bacteria are indolent, vancomycin therapy can be safely delayed for 24 to 48 hours in most patients until a vancomycin-requiring gram-positive infection is identified.

Indications for initial empirical vancomycin therapy include serious catheter-related infections, known colonization with penicillin-resistant pneumococci or methicillin-resistant *S. aureus*, and positive blood culture for gram-positive organisms before final identification and susceptibility testing. Other indications include shock, severe mucositis, prior fluoroquinolone prophylaxis, and institutions in which methicillin-resistant *S. aureus*, vancomycin-susceptible enterococci, and *S. mutis* are frequent pathogens.

Amphotericin B (and its lipid formulations) is the drug of choice for treatment of invasive fungal infections in patients with neutropenia. Up to one third of febrile neutropenic patients not responding to 1 week of antibiotics have systemic fungal infections, usually *Candida* or *Aspergillus*. Antifungal agents, such as caspofungin, voriconazole, or posaconazole, may be indicated in selected cases. Empirical use of fluconazole is not recommended because of lack of activity against *Aspergillus* and some *Candida* species.

**Cell Stimulation Therapy.** To prevent and treat neutropenia, some centers routinely use human recombinant hematopoietic or colony-stimulating growth factors (G-CSF-filgrastim, pegfilgrastim; GM-CSF-sargramostim) to stimulate the proliferation and maturation of bone marrow progenitor cells and increase the number and function of these committed cell populations. Although safe and well tolerated, they are very expensive. Treatment with these agents after chemotherapy may shorten the hospital stay and the duration of fever, but no good evidence exists that they prolong survival or affect the frequency of severe infections. Many authorities recommend that use of these agents should be limited to high-risk neutropenic patients, such as those with severe sepsis, multiorgan failure, or recurrent febrile neutropeia and elderly patients.

**Risk Assessment for the Patient with Febrile Neutropenia, Including the Concept of Brief Observation and Early Discharge of the Low-Risk Patient.** Febrile neutropenic cancer patients can be classified into high-risk and low-risk groups. Factors associated with high-risk patients include (1) status as inpatient when fever and neutropenia develop; (2) the presence of comorbid medical conditions; (3) uncontrolled cancer; (4) acute leukemia; (5) hemodynamically unstable; (6) evidence of organ failure; (7) the presence of pneumonia, severe soft tissue infection, infection of a central line, abdominal pain, neurologic or mental status abnormalities; and (8) neutropenia expected to last more than 10 days. These patients should always be treated in the hospital with intravenous antibiotics.

Low-risk patients generally have an excellent outcome with therapy and are clinically stable outpatients with solid tumors, lymphomas, or chronic leukemia who lack any of the high-risk factors noted previously and who are not on fluoroquinolone prophylaxis. Low-risk patients with fever and neutropenia may be treated in the hospital with oral antibiotics, such as ciprofloxacin plus amoxicillin-clavulanate (or ciprofloxacin plus clindamycin in penicillin-allergic patients). Furthermore, oral antibiotic therapy with early discharge is safe and effective in carefully selected low-risk patients. Hospitalization exposes low-risk patients to potential iatrogenic complications and antimicrobial-resistant nosocomial pathogens, and early discharge followed by outpatient treatment allows an improved quality of life. Low-risk patients may be hospitalized initially, stabilized over 12 to 48 hours, and then discharged to continue parenteral or oral antibiotics. Some
Most solid cancer patients who develop fever and infection are not neutropenic. Infections often occur after surgical procedures and may include wound infection, deep abscess, or perforated viscus. Infections may be associated with central venous catheters, urinary catheters, stents, and prosthetic devices. In addition, solid tumor patients with large tumor lesions may develop obstructive infections (of bronchus, bile duct, or ureter). The spectrum of microorganisms includes a wide variety of indigenous organisms (bacterial, fungal, and viral) as well as nosocomial multi-antibiotic-resistant pathogens.

Prompt initiation of antimicrobial therapy in the febrile non-neutropenic solid cancer patient is not always indicated. Rapid surgical intervention may be more important than the urgent initiation of empirical antibiotics. In febrile non-neutropenic cancer patients who are not ill-appearing and have no identified focus of infection, it may be appropriate to obtain cultures and observe the patients. After consultation with an oncologist, some of these patients can be discharged home from the emergency department with close follow-up. Indications for urgent antibiotics in these patients include signs of sepsis, mental status changes, lactic acidosis, shock, abdominal pain, history of splenectomy, or identification of a focal site of infection.

Impaired Cell-Mediated Immunity. The T cell defects resulting from impaired CMI in cancer patients usually result from cancer chemotherapy or corticosteroid treatment. The cancer impairs CMI in patients with Hodgkin’s disease, non-Hodgkin’s lymphoma, and hairy cell leukemia. Bacterial Infections. Listeria monocytogenes is one of the more common bacterial organisms infecting cancer patients with impaired CMI. Listeria infection is also seen in patients with organ transplants, diabetes, cirrhosis, and AIDS and in those receiving high-dose corticosteroids. No early characteristics distinguish Listeria infection from bacteremias caused by other organisms. Meningitis, which may be accompanied by cerebritis or brain abscess, is the most common focus of infection and may present with personality changes or focal neurologic signs. Cerebrospinal fluid examination frequently does not reveal the organism on Gram’s stain, but protein is elevated and pleocytosis is present. Treatment should be with ampicillin and gentamicin. TMP-SMX is the alternative drug for patients with penicillin allergy. Vancomycin is not effective in treating Listeria infections even when showing in vitro susceptibility. Cephalosporins, such as ceftriaxone and cefotaxime, are not active against Listeria. Infections caused by Salmonella species are common in patients with impaired CMI and usually present with fever without or with enteritis. Bacteremia can result in infection of bones, joints, central nervous system, and endovascular devices. Multidrug-resistant Salmonella species are increasing. Treatment usually includes a third-generation cephalosporin or a fluoroquinolone because many isolates have become resistant to ampicillin and TMP-SMX.

Patients with solid tumors, lymphoma, and leukemia (especially hairy cell leukemia) are at increased risk for pneumonia from Legionella species, with the highest risk in cancer patients receiving high-dose corticosteroids. Non-pneumophila species of Legionella (e.g., Legionella micdadei and Legionella bozemanii) are particularly common in these patients. Clinical and radiographic manifestations of Legionella infection in the immunocompromised patient often differ from those in the immunocompetent host. For example, pleuritic chest pain may be a prominent symptom in the former and may mimic pulmonary embolism. These patients can have fever without any other symptoms of pneumonia despite the presence of radiographic pulmonary infiltrates. In addition, the chest radiograph may reveal an expanding pulmonary nodule or cavitation of a nodule or infiltrate rather than the usual lower lobe alveolar filling defects. Hyponatremia (serum sodium <130 mEq/L) is particularly common. Although gastrointestinal and neurologic symptoms and elevated serum transaminase levels are common in patients with Legionella infections, these are not more common in patients with Legionella than in those with other causes of pneumonia. The treatment of choice for immunocompromised patients with Legionella is a fluoroquinolone or azithromycin (alternatively, doxycycline or erythromycin, each combined with rifampin).

Nocardiosis is an uncommon but often severe bacterial infection caused by a weakly acid-fast gram-positive branching filamentous rod. It occurs in cancer patients, in those on high-dose corticosteroids, and in others with defective CMI. Subacute pneumonia with nodular infiltrates is the most common manifestation, but Nocardia may also produce cellulitis, subcutaneous abscesses, meningitis, and brain abscess. Diagnosis requires biopsy, tissue stains, and culture. Treatment is with sulfonamides often combined with other agents.

Mycobacterial Infections. Tuberculosis and other mycobacterial diseases may produce severe disease in those with defective CMI and present as fever of undetermined origin, pneumonia, lymphadenopathy, or skin lesions. It is easily mistaken for signs caused by the patient’s underlying disease or treatment. Disseminated nontuberculous mycobacterial infections are more common in patients with hairy cell leukemia or chronic myelogenous leukemia.

Fungal Infections. Infections with Cryptococcus neoformans and Cryptococcus gattii occur in patients with Hodgkin’s and non-Hodgkin’s lymphoma, chronic myelogenous leukemia, and chronic lymphocytic leukemia, especially those taking high-dose corticosteroids. Patients with HIV infection, solid organ transplants, diabetes, renal insufficiency, and cirrhosis are also at risk, as are patients on prolonged high-dose corticosteroids for connective tissue diseases. Meningitis is the most common manifestation, often presenting with the insidious onset of low-grade fever and subacute (and often intermittent) headache. Many other organ systems can become infected, including the lung, skin, bones, and joints. Diagnosis is made by measuring cryptococcal antigen (not antibody) in serum and CSF and by fungal cultures and tissue biopsy.

Impaired CMI may result in reactivation of Histoplasma capsulatum and Coccidioides immitis with resultant disseminated disease. Infections with Candida species are also common in cancer patients with defective CMI, but disseminated disease is less likely than in patients with neutropenia. Invasive aspergillosis may develop in cancer patients receiving high-dose corticosteroids but not as commonly as in those with organ transplants or prolonged neutropenia. Pneumocystis jirovecii (formerly carinii) pneumonia is most common in patients with AIDS, leukemia, and lymphoma and in patients with solid tumors taking high doses of corticosteroids.

Parasitic Infections. Reactivation of central nervous system infection with the protozoan T. gondii occurs most often in cancer...
Infections. The most common viruses producing serious infections in patients with deficient CMI, almost exclusively in those receiving high-dose corticosteroids.\textsuperscript{74,75} Larvae of the parasite disseminate from intestine to the lung and other organs, including the central nervous system and skin. Wheezing, cough, dyspnea, hemoptysis, and rash are common symptoms. Chest radiographs may show focal or diffuse infiltrates. Dissemination is often accompanied by bacterial infection, usually caused by enteric gram-negative bacilli carried by the parasites from the intestinal tract. Diagnosis includes examination of sputum and stool for parasites. Treatment of choice is ivermectin, with thiabendazole as a less effective alternative.

Viral Infections. The most common viruses producing serious infections in cancer patients with defective CMI are varicella zoster, herpes simplex, and cytomegalovirus.\textsuperscript{76} Visceral dissemination is common in primary varicella in nonimmune immunocompromised children and adults. When a nonimmune immunocompromised child or adult is exposed to varicella, varicella zoster immune globulin (VarizIG, an investigational product available in the United States under an expanded access protocol) can be given within 96 hours of exposure to ameliorate the disease.\textsuperscript{77} Herpes zoster infection is common in cancer patients, particularly those with Hodgkin’s and non-Hodgkin’s lymphoma and leukemia. Disease usually remains localized to the primary dermatome, but dissemination occurs in approximately 11% of patients. Dissemination is usually limited to the skin, but visceral involvement (lung and liver) occasionally occurs. Skin lesions in primary varicella or zoster often become hemorrhagic in these patients.

Reactivation of herpes simplex virus is common, resulting in severe mucocutaneous infection in oral or genital areas. Spread may occur to the esophagus, lungs, or other organs. Herpetic lesions in cancer patients tend to be larger and deeper than those in the immunocompetent patient. Acyclovir given intravenously is the treatment of choice for varicella zoster and herpes simplex infections in immunocompromised patients, but some authorities recommend oral famciclovir or valacyclovir for stable patients.

Cytomegalovirus infection may occur in cancer patients treated with corticosteroids. Measles virus, although uncommon, may produce severe infection with defective CMI. Fever, rash, pneumonia, and encephalitis are common manifestations. Immune serum globulin may be given after exposure to ameliorate disease. Common community respiratory viruses, such as respiratory syncytial virus, influenza, and adenovirus, may produce severe or fatal pneumonia.\textsuperscript{78}

Humoral Immune (B Cell) Defects. Hypogammaglobulinemia is common in patients with chronic lymphocytic leukemia and myeloma. Low immunoglobulin levels predispose to infections with encapsulated bacteria, such as \textit{S. pneumoniae}, \textit{H. influenzae}, and \textit{N. meningitidis}.\textsuperscript{79-82} Pneumonia is the most common manifestation, but sepsis, otitis media, cellulitis, and urinary tract infection may occur. After receiving cytotoxic agents and corticosteroids for treatment, these patients become susceptible to infections associated with impaired CMI as well as bacterial infections caused by \textit{S. aureus} and gram-negative bacilli. Regular infusions of intravenous immunoglobulin may decrease the incidence of infection but do not prolong survival. Patients should receive pneumococcal vaccine, but many do not respond.

Disruption of Natural Barriers. Disruption of natural anatomic barriers (e.g., mucous membranes and skin) by ulcerating tumors, chemotherapy, radiation, diagnostic and therapeutic procedures, and catheters can lead to infection by gram-positive and gram-negative organisms, including anaerobes.\textsuperscript{83} Oral mucositis, a debilitating and intensely painful condition associated with radiation therapy and high-dose chemotherapy, frequently results in serious local and systemic infections, including life-threatening sepsis with viridans streptococci.\textsuperscript{84,85} Cancers may cause partial or total obstruction of body lumens and cavities. Stenosis of a lumen may result from radiation. Bronchial obstruction by tumor can lead to pneumonia. Obstruction of the urinary tract may result in infection. Gastrointestinal tract obstruction can lead to perforation and peritonitis.

Opportunistic Infections Mimicking Neoplasm. Infectious agents can produce laboratory, radiologic, or physical findings that resemble those caused by the spread of tumor. For example, mass lesions in the brain caused by \textit{Nocardia} or \textit{Toxoplasma} can be mistaken for cancer metastases. \textit{Aspergillus}, \textit{Mucor}, \textit{Rhizopus}, and related fungi invade blood vessel walls and produce thrombosis, which may result in Budd-Chiari syndrome (hepatic vein obstruction), nephrotic syndrome, or oculomotor palsy that may be misattributed to the spread of tumor. Renal vein thrombosis can be caused by infection with gram-negative bacilli. \textit{Candida} fungus balls may develop in one or both ureters, producing a picture of postrenal obstructive uropathy. \textit{Histoplasma}, \textit{Pneumocystis}, \textit{Legionella}, \textit{Aspergillus}, \textit{Nocardia}, and other organisms can produce pulmonary nodules and be mistaken for pulmonary metastases.

Pulmonary Infections in the Immunocompromised Patient. In neutropenic cancer patients, pneumonia is commonly caused by gram-negative bacilli early in neutropenia and by fungal organisms such as \textit{Aspergillus} late. In those with impaired CMI, cytomegalovirus, \textit{Pneumocystis}, \textit{Legionella}, \textit{Nocardia}, mycobacteria, and fungal infections predominate. Pneumococcal pneumonia is most common in patients with impaired humoral immunity. Patients with primary lung cancer or with pulmonary metastases from other cancers develop postobstructive pneumonia, lung abscess, and empyema related to \textit{S. aureus}, gram-negative bacilli, and anaerobes. Mimics of pneumonia in the immunocompromised host include pulmonary emboli and infarction, congestive heart failure, metastatic or primary carcinoma, lymphangitic spread of carcinoma, alveolar hemorrhage, leukoagglutinin reactions, and radiation- and drug-induced pneumonitis.\textsuperscript{86} An acute presentation of “pneumonia” suggests bacterial pneumonia, pulmonary emboli, congestive heart failure, or pulmonary hemorrhage. Subacute presentation suggests a fungal, nocardial, mycobacterial, or viral etiology (Table 181-3).\textsuperscript{87,88}

Diabetes

Diabetic patients have increased susceptibility to infection because of defects in immune function, excess substrate for fungal and bacterial growth, vascular insufficiency related to microangiopathy and atherosclerosis, and sensory neuropathy that leads to wound neglect.\textsuperscript{89-91} Neutrophil and monocyte/macrophage functions are impaired in diabetic patients, including adherence to bacteria, chemotaxis, phagocytosis, and intracellular killing. These defects are exacerbated by hyperglycemia and improved by tight glucose control. Although decreased lymphocyte proliferative responses to phytohemagglutinin and certain pathogens are described, cellular immunity appears normal or only minimally affected by diabetes. Humoral immunity is normal in diabetics.\textsuperscript{92,93}

Infections seen with increased frequency in diabetic patients include rhinocerebral zygomycosis (formerly mucormycosis) caused by \textit{Rhizopus} and \textit{Mucor} species; malignant (or necrotizing) otitis externa caused by \textit{P. aeruginosa}; pneumonia caused
Alcoholism and Cirrhosis

Alcohol consumption predisposes to infection through direct suppression of the immune system, alterations in blood flow, depression of mental status, and delay in seeking medical care.64 With alcoholic cirrhosis, there is deficient hepatic clearance and killing of bacteria by reticuloendothelial cells, as well as splenic hypofunction.69 Complement deficiency occurs because the liver is the primary site of C3 synthesis. Neutrophils show impaired recruitment to infective sites and defective chemotaxis and phagocytosis.66,67 Cellular immune deficiency occurs and is exacerbated by malnutrition. Bactericidal activity of IgM antibody against gram-negative pathogens such as E. coli and H. influenzae is decreased.

Acute ethanol intoxication is associated with granulocytopenia and diminished leukocyte mobilization that is reversible with abstinence. Ethanol intoxication interferes with most respiratory tract defense mechanisms, resulting in alterations of normal flora, impaired mechanical and cellular clearance because of a suppressed cough reflex, decreased ciliary motility, and resultant aspiration. These effects are often compounded by malnutrition, cigarette smoking, and chronic lung disease. Alcoholics exhibit an increased incidence of oropharyngeal colonization by gram-negative bacteria (35–59% of ambulatory alcoholic patients) compared with control subjects (14–18%). Alcoholics are also more likely to aspire because of loss of reflex glottic closure associated with acute intoxication, withdrawal seizures, and encephalopathy.

Common infections include spontaneous bacteremia and sepsis caused by E. coli, K. pneumoniae, Salmonella, streptococci, Vibrio vulnificus, and Aeromonas; spontaneous bacterial peritonitis, usually caused by E. coli, K. pneumoniae, S. pneumoniae, or enterococci; pneumonia related to pneumococci, gram-negative bacilli (E. coli, K. pneumoniae, and H. influenzae), and anaerobes; tuberculosis; meningitis caused by S. pneumoniae and L. monocytogenes; and skin and soft tissue infections with S. aureus, streptococci, and gram-negative bacilli. Nasopharyngeal and cutaneous diphtheria also occur.98

Renal Failure

Infections cause up to 20% of all deaths among patients with chronic renal failure and are the second most common cause of mortality after coronary artery disease.99,100 Disruption of cutaneous barriers at vascular access sites and peritoneal dialysis catheter sites as well as numerous immune system defects are responsible for the increased incidence of infection. Uremic pruritus with excoration, epidermal and sweat gland atrophy, dryness, and vesicular eruptions also compromise the cutaneous barrier. Reduced renal clearance of unknown toxins, nutritional deficiencies, and administration of immunosuppressive medications lead to aberrant immune regulation early in the course of renal failure.

Chronic kidney failure leads to a state of generalized immune hyporesponsiveness. Neutrophils show reduced mobility, chemotaxis, adherence, phagocytosis, and intracellular bactericidal activity, and leukopenia is commonly present. CMI is severely impaired, with decreased activation and proliferation of T lymphocytes and reduced NK cell activity, which cannot be reversed by hemodialysis. Furthermore, humoral immunity is adversely affected, resulting in deficient production of certain IgG subclass antibodies. Poor response to vaccines is common but can be improved by reinforced vaccination schedules, increased vaccine dosage, and adjunct immunomodulators.101

Additional predisposing factors to infection in uremic patients include low serum albumin, iron overload, increased intracellular calcium, circulating low-molecular-weight uremic toxins, metabolic acidosis, circulating inhibitors to chemotactic factors, decreased production of endogenous pyrogens, and invasive vascular procedures for dialysis access. The annual mortality rate from sepsis in dialysis patients is increased 100 to 300 times.102

Skin and soft tissue infections, especially those caused by S. aureus, are particularly severe in diabetics and in those with peripheral vascular disease or peripheral neuropathy. Vascular access site infections are usually caused by S. aureus but occasionally by gram-negative bacilli and enterococci. Patients using central venous catheters for dialysis have much higher rates of sepsis compared to fistulas or grafts. Bacteremia may lead to hematogenous osteomyelitis, usually involving the ribs or thoracic vertebrae, as well as endocarditis, meningitis, epidual abscess, and septic arthritis. Although the incidence of pneumonia is not increased overall in renal failure, it is often more severe, and there is an increased incidence of Legionella pneumonia. Tuberculosis as well as fungal infections caused by Candida species, Cryptococcus, Histoplasma, and Coccioidoides occur with increased frequency. In addition, C. difficile colitis occurs more frequently and is more severe in patients with chronic renal failure. Infections of the urinary tract are more prevalent, with urinary bladder catheterization the most frequent predisposing factor. There is a poor correlation between the presence of pyuria and urinary tract infection in these
patients. Candida infection of the urinary tract may develop in patients with chronic renal failure treated with broad-spectrum antibiotics.

Up to two thirds of patients receiving chronic ambulatory peritoneal dialysis have peritonitis in their first year, and one third may be forced to discontinue dialysis because of recurrent infections. S. aureus and S. epidermidis predominate, followed by streptococci, gram-negative bacilli, and Candida species. Fortunately, peritoneal dialysis patients have much lower rates of sepsis than those on hemodialysis.

Splenectomy, Hyposplenism, and Functional Asplenia

The spleen is the most important organ in the reticuloendothelial system and the primary site for IgM synthesis, the first early immune response of the body. Opsonin production in the spleen facilitates phagocytosis of bacteria by intracellular macrophages. Patients without a spleen also have decreased production of neutrophils, NK cells, and immunomodulating cytokines. The spleen is the principal site of clearance of S. pneumoniae from the blood. Splenectomy or functional asplenia predisposes to overwhelming pneumococcal infection and fulminant infection with other encapsulated organisms (H. influenzae, N. meningitidis, and Capnocytophaga canimorsus after dog bites) and gram-negative bacilli (E. coli and P. aeruginosa). Asplenic people who become infected with Babesia microti, a malaria-like protozoan transmitted by tick bite in the United States, develop severe and often fatal hemolysis. Human granulocytic anaplasmosis (formerly ehrlichiosis), another tick-borne infection, is severe and sometimes fatal in asplenic patients. In addition, the gram-negative cocccobacillus Bordetella holmesii produces a non-life-threatening acute febrile illness with bacteremia in patients with asplenia. Pneumococcal sepsis represents 50 to 90% of cases. Most healthy adults who die after fulminating pneumococcal sepsis have had a splenectomy or have a congenitally small or abnormal spleen.

Overwhelming postsplenectomy sepsis is rare, and the true incidence is unknown due to lack of prospective studies. The risk is greater in children than in adults, with children younger than 2 years at greatest risk. The risk is highest in the first few years after splenectomy but persists throughout life into old age. People undergoing splenectomy for a hematologic disorder or lymphoma are at much higher risk for overwhelming postsplenectomy infection (OPSI) than are those undergoing splenectomy for trauma. This is probably because of the occurrence of splenic implants (splenosis) or accessory spleens in traumatized patients. Patients with functional asplenia from sickle cell anemia or thalassemia major are at high risk for overwhelming bacterial infections as well.

Functional hyposplenism occurs in a variety of conditions besides sickle cell disease, including sickle cell–hemoglobin C disease, ulcerative colitis, celiac disease, sarcoidosis, amyloidosis, rheumatoid arthritis, and SLE. The presence of anatomic or functional hyposplenism may be recognized by finding Howell-Jolly bodies in red blood cells on a peripheral blood smear.

When OPSI occurs, often no obvious source of infection is found. Prodromal symptoms, such as fever, rigors, malaise, myalgias, headache, vomiting, and diarrhea, may be present for 1 or 2 days. Patients seen at this time may be misdiagnosed as having a viral illness, gastroenteritis, or food poisoning. Abrupt deterioration then occurs over hours, with rapid progression to septic shock with disseminated intravascular coagulation, purpura, and multiorgan dysfunction. The mortality rate is high (50–70%), with younger children having the highest mortality rate. In addition, meningitis without overwhelming infection or shock is a common presentation of pneumococcal infection in asplenic patients. When fever develops in a person at risk for this disorder, treatment with an antimicrobial agent effective against S. pneumoniae should be initiated without delay. After blood culture is performed, the patient should receive ceftriaxone or cefotaxime, with addition of vancomycin in areas where penicillin resistance is prevalent. Clindamycin, levofloxacin, and moxifloxacin are alternatives for patients with serious penicillin allergy.

Use of pneumococcal vaccine in patients at risk is especially important now that antimicrobial-resistant S. pneumoniae is prevalent. Asplenic people should be immunized against pneumococcus, H. influenzae type B, N. meningitidis, and influenza virus. People with functional hyposplenism related to serious underlying diseases often respond poorly to pneumococcal vaccine. Children should receive prophylaxis with oral penicillin or amoxicillin up to age 5 years and for at least 1 or 2 years after splenectomy, provided that they have not had an invasive pneumococcal infection and have received pneumococcal immunizations. Long-term antimicrobial prophylaxis is generally not recommended in adults. These patients should have standby oral antibiotics at home (amoxicillin-clavulinate, levofloxacin, or moxifloxacin) with instructions to self-administer at the first sign of infection, and they should be provided with information and a medical alert bracelet. Fatal pneumococcal infection has occurred in patients immunized with pneumococcal vaccine who were also taking penicillin.

An emergency department–based pneumococcal vaccine program, if implemented, could reduce mortality in high-risk patients while remaining cost-effective.

IMMUNOSUPPRESSIVE THERAPY

Corticosteroids

High doses of corticosteroids alter the distribution and function of neutrophils, monocytes, and lymphocytes. Corticosteroids suppress inflammation and enhance susceptibility to infection by impairing the mobilization and function of neutrophils and mononuclear cells at sites of primary lodgment of microorganisms in tissues. Corticosteroids inhibit neutrophil adherence to endothelium, decrease chemotaxis of neutrophils and monocytes, and inhibit phagocytosis and intracellular killing of microorganisms. Corticosteroids also severely impair CMI, probably a result of inhibition of the migration of lymphocytes to the site of antigen challenge, inhibition of lymphokine production, and consequent inhibition of lymphocyte proliferation. They also inhibit both classical and alternative pathways of complement activation. The hyperglycemia that occurs with corticosteroid use also contributes significantly to infection risk. Moreover, patients receiving high-dose corticosteroids have infection risks related to anatomic abnormalities of the underlying disease, treatment with other immunosuppressive agents, cancer chemotherapeutic agents, radiation, and implantation of foreign bodies.

Acute administration of corticosteroids produces marked alterations in circulating leukocyte numbers. Basophils, eosinophils, and monocytes decrease, whereas neutrophils are increased. These changes occur within 4 to 6 hours and abate by 24 to 48 hours after a single steroid dose. There is a redistribution of lymphocytes, predominately T cells, out of the circulation, resulting in lymphocytopenia. Acute or chronic corticosteroid therapy has little effect on serum immunoglobulin levels.

The most common infections occurring in patients receiving high-dose corticosteroids are those caused by pyogenic bacte-
ria (S. aureus, streptococci, and gram-negative bacilli). Despite the profound depression of CMI that occurs in patients taking corticosteroids, these patients generally have few infections commonly recognized as associated with defective CMI. The most common are tuberculosis and severe or disseminated infections caused by varicella zoster and herpes simplex viruses. Patients receiving moderate doses of corticosteroids for asthma and other disorders are at increased risk for lethal primary varicella infection.\(^{110}\) Other infections seen with corticosteroid use include those caused by Listeria, Salmonella, Legionella, Nocardia, Candida, Aspergillus, Cryptococcus, Histoplasma, Coccidioides, Pneumocystis, Toxoplasma, Cryptosporidium, and Strongyloides. Patients with neurologic diseases have much higher rates of infectious complications than patients with intestinal, hepatic, or renal disease. The infectious complications related to corticosteroid use increase with doses of prednisone equivalents of greater than 20 mg/day in adults, with total doses of more than 700 mg, and with treatment longer than 30 days. The risk of adrenal suppression can be decreased by using prednisone doses less than 7.5 mg/day, giving doses early in the day, avoiding split doses, and using alternate-day dosing.

Corticosteroids decrease leukocyte accumulation at inflammatory sites, and the whole cascade of responses leading to local manifestations of infection is slowed. These effects result in late presentation of serious infections. The ability of parietal cavities to localize sepsis is reduced. In addition, prolonged administration of corticosteroids results in delayed wound healing. For example, skin sutures should be left in place 50% to 100% longer than in normal patients. Short-term treatment has little effect on wound healing.\(^{120}\)

The diagnosis of peritonitis resulting from perforation of colonic diverticula, appendicitis, peptic ulcer, or another primary intra-abdominal condition is particularly difficult.\(^{121}\) These patients have abdominal discomfort, but they may have few abdominal findings and need rapid and aggressive investigation for life-threatening abdominal disease. CT scan of the abdomen and pelvis and surgical consultation may be needed emergently in these patients. Broad-spectrum antimicrobials to cover for gram-negative enteric bacilli and anaerobes should be administered without delay.

Other complications unrelated to the effects on the immune system include iatrogenic Cushing’s syndrome, peptic ulcer disease, benign intracranial hypertension (pseudotumor cerebri), glaucoma, posterior subcapsular cataract, pancreatitis, avascular necrosis of bone (especially the femoral and humoral heads), psychosis, poor wound healing, hyperglycemia, diabetic ketoacidosis, hyperosmolar nonketotic diabetic coma, myopathy, and osteoporosis, resulting in vertebral compression fractures and other spontaneous fractures. In addition, adrenocortical insufficiency may occur on withdrawal of therapy.

Other Immunosuppressive Medications

Commonly used immunosuppressives include cyclosporine, tacrolimus, sirolimus, mycophenolate, azathioprine, methotrexate, and cyclophosphamide. They treat a wide variety of conditions, including rheumatoid arthritis, psoriasis, nephrotic syndrome, and inflammatory bowel disease, and they are used in the prevention and treatment of organ transplant rejection.\(^{122}\) These drugs depress immune function, especially CMI. In addition, they have a narrow therapeutic window, wide-ranging toxic side effects, and many significant drug-drug and drug-food interactions. Patients may present to the emergency department for evaluation of symptoms caused by an adverse drug reaction or an infection. Before altering current medications, the physician needs to check carefully for drug interactions. For a more detailed discussion of the toxic effects of these agents, refer to Chapter 182.

New immunomodulating agents that inhibit tumor necrosis factor, interleukins, and other cytokines treat a variety of immune-mediated inflammatory diseases, including rheumatoid arthritis, psoriasis, and inflammatory bowel disease. These drugs include infliximab, etanercept, adalimumab, rituximab, basiliximab, daclizumab, abatacept, anakinra, and leflunomide. Serious infections, including bacterial sepsis, are reported after treatment with several of these agents, especially reactivation of latent M. tuberculosis infection, frequently disseminated and extrapulmonary at presentation.\(^{123-127}\) These drugs may also cause impaired wound healing, so skin sutures should be left in place for a longer amount of time than is usual.\(^{128}\)

**KEY CONCEPTS**

- Fever in cancer patients with chemotherapy-induced neutropenia indicates infection until proved otherwise, most often caused by gram-positive and gram-negative bacteria but also by a wide variety of fungal, viral, mycobacterial, and protozoal organisms.
- Rapid diagnosis and early initiation of therapy are essential in preventing serious morbidity and mortality in immunocompromised patients who often have subtle or unusual presentations and are difficult to diagnose. Early use of broad-spectrum antibiotics is indicated after appropriate cultures of all potential sites of infection, including intravascular catheters.
- Diabetics, alcoholics, and patients with renal failure, cirrhosis, and collagen vascular diseases all have varying degrees of immunosuppression.
- Patients with functional or surgical asplenia are at high risk for overwhelming sepsis from encapsulated bacteria, especially pneumococci.
- High doses of corticosteroids cause profound dysfunction of neutrophils and mononuclear cells and impair cell-mediated immunity, resulting in a marked increase in infections caused by pyogenic bacteria, varicella zoster and herpes simplex viruses, tuberculosis, and a wide variety of other bacteria, fungi, and parasites.

The successful rehabilitation of patients with end-stage renal, pulmonary, hepatic, and cardiac failure through organ transplantation is one of the great achievements of modern biomedical science. Because 1-year survival rates for all solid organ transplants exceed 80% and many patients survive much longer, increasing numbers of transplant patients with complications are being seen in the emergency department (ED).

**PRINCIPLES OF DISEASE**

Transplanted organs are devoid of their native innervations and have surgical anastomoses to a variety of structures, including vessels, heart chambers, bronchi, ureters, intestines, and even the bladder, depending on the allograft. Pain is therefore an unreliable sign of underlying disease. Furthermore, the normal inflammatory and immunologic responses to infection and malignancy are impaired. Subtle symptoms and signs may be the harbingers for serious complications of organ transplant, and each complaint merits careful investigation. Even in the most advanced stages of severe disease, patients may have few specific complaints and physical findings. Anatomic relationships must be considered to anticipate leakages or blockages of vital anastomoses. The baseline physiologic capacity of the allograft will aid in interpreting chief complaints in the context of possible organ failure. Small changes in allograft function may be a harbinger of an episode of rejection.

Transplant organ complications can generally be classified into one of four categories: anatomy, infection, rejection, and drug toxicity. In any transplant patient presenting to the ED, each category must be considered in the differential diagnosis. Often, the exact etiology is not determined until the patient is admitted to the hospital. Time since transplant must also be considered in the evaluation. This information can help the clinician focus his or her investigative efforts and tailor treatment regimens.

**Infection**

Lifelong immunosuppression is generally necessary for all recipients of solid organ transplants. Because of this, infection is the primary cause of mortality after transplantation. Two thirds of transplant patients have at least one significant infection, most commonly nosocomial during the surgical recovery period or subsequently community acquired (Box 182-1).1,2

Signs of infection in this patient population are often blunted by an impaired inflammatory response. Minimal complaints or the chief complaint of a fever in an afebrile patient may herald a severe infection. Aggressive management usually translates into increased patient survival and graft function.7

Primary sources of infection in transplant recipients include pretransplant, community acquired, transmission from organ donor, and nosocomial. Transplant patients may be vaccinated,
Infectious Pathogens in Transplant Patients

Exposure before Transplantation
- Tuberculosis
- Histoplasmosis
- Coccidioidomycosis
- Blastomycosis
- Strongyloides stercoralis
- Hepatitis B and C
- Human immunodeficiency virus
- Cytomegalovirus (CMV)
- Epstein-Barr virus (EBV)
- Varicella zoster virus
- Herpes simplex virus

Community-Acquired Exposure after Transplantation
- Influenza
- Primary varicella
- Salmonellosis
- Tuberculosis and fungal infections (see above)
- Legionellosis
- Nocardiosis
- Cryptococcosis
- CMV
- EBV

Nosocomial Exposure
- Aspergillosis
- Legionellosis
- Pseudomonas aeruginosa and other gram-negative bacilli

but live viral antigens should be avoided. Close family members should not be given live vaccines due to the risk of transmission. The timing of infection can be separated into three periods: first month post-transplant, between 1 and 6 months post-transplant, and more than 6 months post-transplant. These distinctions are helpful in predicting the etiologic agents of the infection.

First Month after Transplant
Infections occurring in the first month after transplantation are likely to be related to the transplant procedure, catheters, and intubation. In addition, the typical causes of postoperative fever must always be considered in the workup. Nosocomial pathogens are prominent, and management is similar to that for any immunosuppressed patient recently discharged from the hospital.

1 to 6 Months after Transplant
Infections occurring from 1 to 6 months after transplant are divided into two general types: immunomodulating viral infections and opportunistic infections. Immunomodulating viruses include cytomegalovirus (CMV), hepatitis B and C, BK polyomavirus, human herpesvirus 6, and Epstein-Barr virus (EBV), whereas opportunistic infections include Pneumocystis, Listeria, and fungal species.

CMV is the most important and prevalent immunomodulating virus 1 to 6 months after transplantation. CMV infection may produce disease in multiple systems, but pneumonitis is particularly common and may present insidiously. CMV infection may be primary or due to reactivation from latent viral particles found in lymphocytes. Typically, signs of CMV infection occur at a median of 40 days after transplant. Survival from CMV infection is improving due to earlier diagnosis from aggressive use of bronchoscopy and treatment with gancyclovir and CMV-specific immunoglobulin. Prophylaxis with gancyclovir reduces CMV incidence and death due to infection, but the use of routine gancyclovir is associated with a number of potential unwanted side effects. Because the risk of CMV infection is greatest during antilymphocyte therapy, some transplant centers only administer gancyclovir selectively during the treatment period. Despite these advances, however, CMV infection is still often fatal.

Active CMV infection can also trigger or exacerbate organ rejection. CMV is linked to a particular form of glomerulopathy in renal allograft recipients, as well as acute hepatic dysfunction and the disappearing bile duct syndrome of chronic hepatic allograft dysfunction. Furthermore, both acute cardiac dysfunction and accelerated coronary artery atherosclerosis of chronic heart transplant rejection are linked to CMV.

EBV infection causes similar clinical effects as those caused by CMV. EBV contributes to the net state of immunosuppression and can cause a mononucleosis-like syndrome associated with lymphadenopathy, weakness, and low-grade fevers. Because CMV and EBV often coexist, it is unknown whether EBV alone causes or triggers graft rejection independently. EBV is also implicated in B cell lymphoproliferative syndrome, which is histologically similar to polymorphic B cell lymphoma.

6 Months after Transplant
Six months or more after transplant, patients with functioning solid organ allografts receiving immunosuppression therapy are divided into three groups relative to infection susceptibility: healthy transplant, chronic viral infection, and chronic rejection.

Healthy Transplant. Healthy transplant patients have no chronic immunomodulating viral infections and a functioning allograft. They have a mildly increased susceptibility to normal community-acquired infections, such as influenza, urinary tract infection, and pneumococcal pneumonia.

Chronic Viral Infection. Progressive disease may develop as a result of the combination of viral immunomodulating infections and long-term immunosuppression. Progressive liver disease due to recurrent or acquired viral hepatitis may occur as well as hepatocellular carcinoma. B cell lymphoproliferative disorder associated with EBV infection may also develop.

Primary varicella infection may lead to rapid dissemination with pneumonia, pancreatitis, hepatitis, encephalitis, and disseminated intravascular coagulation. Patients who are varicella zoster virus (VZV) seronegative need high doses of intravenous (IV) varicella zoster immune globulin after any exposure. Therapy can be lifesaving if it is administered early before dissemination occurs.

Reactivation of latent VZV infection, manifested as cutaneous herpes zoster, affects at least 10% of solid organ transplant recipients. Fortunately, reactivation of VZV is usually confined to a single dermatome and does not disseminate. Hospitalization for IV acyclovir therapy should be considered because this speeds healing but does not change the incidence of painful neuralgia. Facial zoster specifically involving the cornea, however, and disseminated infections found in more than one dermatome are indications for admission.

Herpes simplex virus (HSV) reactivation is common after solid organ transplants and can manifest as oral or anogenital lesions, more often ulcers than vesicles. Some transplant centers prescribe oral acyclovir for 3 to 6 months after transplantation, whereas others choose to treat HSV immediately.
Disseminated toxoplasmosis is a particular problem in heart transplant patients. Toxoplasmosis can lay dormant in the tissues, especially the heart, and be reactivated during immunosuppression, resulting in myocarditis, brain abscesses, or diffuse encephalitis. Typically, treatment of toxoplasmosis is a combination IV sulfadiazine and pyrimethamine daily for more than 4 weeks.

_Strongyloides stercoralis_, an intestinal nematode that normally causes few or no symptoms, can become an invasive pathogen. During immunosuppression, a hyperinfection syndrome can develop, causing a necrotizing hemorrhagic enterocolitis. The exaggeration of the parasite’s normal life cycle has a major impact on the GI tract and lungs (hemorrhagic pneumonia). Disseminated strongyloidiasis occurs when the larvae migrate from the GI tract into all portions of the body. Dissemination and hyperinfection are associated with gram-negative bacteria and meningitis secondary to impairment of the blood-gut barrier.

Mycobacterial disease can present as opportunistic reactivation or a primary infection. Even disseminated disease can be clinically silent, with invasion of the bowel, skin, and GI tract. Pulmonary disease can be absent, miliary, or cavitary (Fig. 182-2). Treatment is a significant problem because typical agents used to treat mycobacteria can cause graft dysfunction.1,2

Rejection

The course of rejection may vary from patient to patient, but each individual typically has a lifelong course of a waxing and waning immune response to the allograft, mandating ongoing surveillance of allograft function. Differentiating infection and rejection is often difficult. Determination is made only after biopsy of the transplanted organ or positive culture results are identified.

Rejection typically occurs in three phases: hyperacute, acute, and chronic. Hyperacute rejection is rare with careful donor-recipient matching. It typically occurs in the immediate perioperative period. Acute rejection occurs within the first

Figure 182-2. A 22-year-old male with a kidney transplant who presents with fever and a cough who was diagnosed with reactivated tuberculosis by sputum analysis.
months after transplantation. It usually presents with constitutional symptoms and signs of transplant organ insufficiency. Expeditious laboratory assessment, including possible allograft biopsy, can confirm the diagnosis of rejection, and the appropriate adjustment can be made in the patient’s immunosuppressant regimen. Acute rejection can occur at any time if immunosuppressants are stopped. Chronic rejection has a time course of years and results in the gradual failure of the transplanted organ.12

Drug Toxicity/Immunosuppression
Pharmacology of Immunosuppression

The greatest advancement in the treatment of patients with transplanted organs is the advent of effective immunosuppressants. Immunosuppressive therapy requires correctly timed drug combinations to establish a delicate balance between immunosuppression, rejection, and susceptibility to infection. Multiple agents are used, and patients are commonly on more than one agent. Regimens are typically transplant center specific, but must include a calcineurin inhibitor, an antimetabolite, and varying dosages of steroids. Recognizing the side effects, toxicities, and potential drug interactions of immunosuppressant medications is an important component in the care of any transplant patient.

Allogeneic bone marrow transplantation from the solid organ donor is being investigated as a means of immunosuppression. If successful, bone marrow transplantation may revolutionize how solid organ rejection is treated and how immunosuppression is achieved.

Calcineurin Inhibitors
Cyclosporine. A variety of immunosuppression strategies are being tested, but the current mainstay of transplant immunosuppression is cyclosporine.13,14 Cyclosporine inhibits both cellular and humoral immunity by binding to cycophilins, which block cytokine transcription and production, thereby inhibiting lymphocyte signal transduction. The result is a potent immunosuppression of helper-inducer T cells, without affecting the suppressor T cell subset.13,15 The helper-inducer T cells enhance antibody recognition and production by B cells.

Cyclosporine has significant risks. It exhibits dose-related nephrotoxicity, which is additive to other nephrotoxic drugs typically used after transplant, such as amphotericin B, aminoglycosides, and high-dose TMP-SMX. Cyclosporine causes renal tubular injury and direct renal artery vasospasm in a dose-dependent manner, leading to systemic hypertension in many recipients.13 Hypertension must be treated aggressively using standard regimens to preserve renal function and prevent atherosclerosis. Cyclosporine may also aggravate hyperlipidemias, leading to atherosclerosis.16 Therefore, monitoring blood levels and renal function is routine during therapy.

Cyclosporine causes hyperuricemia and gout in transplant patients. The nephrotoxic effects of cyclosporine complicate the management of gouty attacks in renal transplant patients.17

Cyclosporine levels are altered by many common post-transplant medications (Table 182-1). Drugs that inhibit cytochrome P450 metabolism, such as erythromycin and ketoconazole, produce elevated cyclosporine levels and enhanced toxicity.18 Treatment with rifampin can increase metabolism, which triggers episodes of organ rejection. Cyclosporine also causes hepatotoxicity, hyperkalemia, hirsutism, tremor, and gingival hyperplasia.13

Tacrolimus. Tacrolimus is a macrolide compound that binds to lymphocyte proteins and inhibits cytokine synthesis. Used as either primary or rescue therapy for allograft rejection, tacrolimus is effective for rejection in all types of solid organ transplants.19,20 Due to an improved side effect profile and more effective immunosuppression, tacrolimus is more commonly used. Of patients discharged after liver transplantation in 2002, more than 88% had tacrolimus in their regimen.21

As with cyclosporine, tacrolimus causes nephrotoxicity as well as neurotoxicity. In combination with steroids, tacrolimus is more likely than cyclosporine to lead to diabetes. Tacrolimus can also cause anorexia, diarrhea, dyspepsia, and nausea. Macrolide antibiotics should not be prescribed to patients taking tacrolimus because they may cause increased levels of tacrolimus, leading to potential toxicity.19

Antimetabolites
Azathioprine. Azathioprine is an antimetabolite derivative of 6-mercaptopurine. Long an important component of immunosuppressive therapy in solid organ transplants, azathioprine functions by inhibiting both deoxyribonucleic acid and ribonucleic acid synthesis, resulting in a suppression of lymphocyte proliferation. It is typically used in combination with other agents.22 Since the introduction of the calcineurin inhibitor class, the use of azathioprine has been reduced due to an improved side effect profile.

Azathioprine is a bone marrow toxin, and patients exhibit dose-related neutropenia. The drug is given at the minimum effective dose to maintain a peripheral white blood cell count of 4000 to 6000/mL. Azathioprine may also cause hepatic dysfunction and other GI disturbances.23

Mycophenolate Mofetil. Mycophenolate mofetil (MMF) prevents and suppresses organ rejection after solid organ transplantation.21,24 MMF is an antimetabolite with more potent and selective inhibition of lymphocytic proliferation. It reduces the incidence of acute rejection but with no significant change in the long-term survival of transplant recipients or their allografts.19,22

MMF has the advantage of a low side effect profile, and it should be used concomitantly with cyclosporine and corticosteroids when the patient can tolerate oral medication. The

Table 182-1 Drug Interactions with Cyclosporine
OKT3 toxicity is common because of T cell activation and lymphokine release caused by these agents. When receiving these agents, patients are at increased risk of infection with opportunistic pathogens, particularly CMV. An increased risk of lymphoproliferative disease also exists.23,26

### SPECIFIC DISORDERS

#### Clinical Features

The pertinent clinical features of organ transplant complications are as extensive as the elements of the history and physical examination. Allograft rejection symptoms are usually vague and nonspecific. Complications of the organ often result in localized symptoms and dysfunction of the allograft. The clinical features of infectious complications depend on the nature of the pathogenic organism, location of the infection, and level of immunosuppression. The resuscitation of a traumatized transplant patient should focus on standard injury patterns. However, careful attention must be paid to maintaining the appropriate level of immunosuppression and watching for the typical transplant-related complications.27 Every complaint and finding in the organ transplant recipient must be examined in the most suspicious light to avoid missing catastrophic illness.

#### Diagnostic Strategies

Transplant patients should undergo careful and often extensive laboratory and radiographic evaluation to rule out myriad infectious etiologies, assess allograft function, and survey for signs of drug toxicity. Laboratory assessments should include organ-specific measures of function as well as a careful search for evidence of infection. When suspected, appropriate cultures and serologies should be obtained. Radiologic interventions focus on sources of infection and the relevant anatomy of the patient’s allograft.

#### MANAGEMENT

### Heart Transplant

#### General Approach

Human heart transplantation was first performed in 1967. More than 3000 procedures are done annually in the United States. The 5-year survival rates for adults and children are 72 and 80%, respectively.28 Typically, the recipient heart is removed and replaced by the donor heart (orthotopic transplant), but occasionally the recipient heart is left in place with the donor heart anastomosed to the native vessels (heterotopic transplant) (Fig. 182-4).

Patients are usually discharged from the hospital within 2 or 3 weeks. In the Stanford experience, 37% of heart transplant patients made at least one ED visit in the ensuing 3 years (range, one to six visits). The most common complaints are fever (37%), shortness of breath (13%), GI problems (nausea, vomiting, and diarrhea) (10%), and chest pain (9%). Sixty percent of these patients are admitted, compared with an overall ED admission rate of 15%, reflecting an appropriately high concern for rejection or localized or systemic infection. The most common ED diagnoses are sepsis (18%), rejection (11%), and pneumonia (8%).16

In trauma, the diagnosis of myocardial contusion is established in these patients by usual means, notwithstanding the lack of a gold standard. Treatment for the transplanted heart should not differ from that for native hearts. Baseline tachy-
cardia is expected, due to denervation of the vagus nerve. Despite the absence of a pericardium, scarring and adhesions may result in clinical tamponade with pericardial fluid or blood. Blind pericardiocentesis is discouraged.27

Infection and rejection are the leading causes of mortality in the first year. Any heart transplant patient presenting to the ED with congestive heart failure (CHF), fever (>38°C), shortness of breath, hypoxia, hypotension, poorly controlled hypertension, or new dysrhythmia should be admitted. Chest pain is rarely related to cardiac ischemia because the denervated heart is incapable of producing angina.29 Accelerated atherosclerosis of the graft vessels is the hallmark of chronic rejection. Ischemia is manifested as CHF, ventricular dysrhythmias, hypotension, syncope, or sudden death.30,31 CMV infection also appears to be a risk factor for accelerated atherosclerosis.9,18,32

Drug Toxicity

Lifelong immunosuppression is required in these patients. Most centers use a three-drug regimen of cyclosporine, prednisone, and azathioprine. Each drug has potential for toxicity, and the combination of cyclosporine and prednisone aggravates the hyperlipidemias common to many of these patients.16,33

Rarely, cyclosporine toxicity can result in a neurotoxic syndrome of seizures, confusion, cortical blindness, and quadriplegia, possibly progressing to coma. Seizure management is with standard anticonvulsants.34-36

Rejection

Acute rejection occurs in 75 to 85% of patients within the first 3 months. Its manifestations may be subtle with cyclosporine included in the immunosuppressive regimen. Previously, rejection was obvious, with decreased QRS voltage, a new S3 heart sound, or new-onset CHF or atrial dysrhythmias. These features are now present only during episodes of severe rejection, and the diagnosis of rejection is made by endomyocardial biopsy showing lymphocyte infiltration or myocyte necrosis.1,16
Because most episodes of early or mild rejection are asymptomatic, frequent biopsies are performed to monitor the success of the immunosuppressive regimen.37,38

Acute rejection is treated with increased doses of corticosteroids (methylprednisolone, 500–1000 mg/day) and cyclosporine or with OKT3 or antithymocyte globulin. Immunosuppression is continued lifelong, with endocardial biopsies at least every 3 to 6 months.36,39

The transplanted heart maintains a rate of 100 to 110 beats/minute without parasympathetic tone. The electrocardiogram...
A 68-year-old male status post heterotopic heart transplant; native heart rate of 55 and donor heart rate of 75 beats per minute.

(ECG) typically demonstrates two P waves. One wave is from the native sinus node in the posterior right atrium, which is often left in place. The second P wave is from the donor sinoatrial node, which should conduct to the ventricles as usual with a normal PR interval. In the rare heterotopic heart transplant, bizarre ECGs may be seen that do not conform to normal standards (Fig. 182-5).

The transplanted heart rate can increase with exercise or stress through the effects of endogenous catecholamines, up to 70% maximum for age. Exogenous pressor drugs work well in the transplanted heart. Up-regulation of beta-adrenergic receptors appears to occur in the graft, with a slightly enhanced response to norepinephrine and isoproterenol. Typical antihypertensive agents can be used as in the nontransplant patient. Atropine is ineffective due to vagal denervation.

Infection

Infection in heart transplant patients has many causes. One fourth of deaths after transplant result from infection. The most vulnerable period is the first 3 months, when immunosuppression is maximal. Although one third of patients will have a major infection develop in the first year, life-threatening infection after 1 year is rare. In the first month, nosocomial infection predominates, with the usual gram-positive and gram-negative bacteria. After the first 3 months, patients experience an overall 20% per year rate of infection. The most common skin infection is herpes zoster, which is treated with high-dose acyclovir. Nausea, vomiting, or diarrhea should prompt a search for CMV by culture and serologic testing.

Any new headache with or without visual changes may be the first symptom of meningitis or brain abscess, and CT scan of the head and a lumbar puncture should be obtained. Fever, lethargy, headache, altered mental status, or seizures are presenting signs of Listeria, cryptococcal meningitis, Toxoplasma gondii, or brain abscesses from Nocardia or Aspergillus. A more definitive diagnosis can often be made through biopsy of a mass lesion or drainage of an abscess. This often obviates the need for lumbar puncture. Aseptic meningitis occurs in 10 to 14% of patients treated with OKT3 approximately 6 to 10 days after therapy.

Due to the attendant risk of endocarditis, antibiotic prophylaxis should be provided for invasive procedures likely to cause bacteremia, such as abscess drainage and urethral catheterization. Endotracheal intubation requires no such prophylaxis. VZV immune globulin is recommended as soon as possible when seronegative patients are exposed to chickenpox or herpes zoster.

Liver Transplant

Liver transplants have 1- and 3-year survival rates of 86 and 76%, respectively. Complications are common, and loss of function of the graft organ is rapidly life-threatening.

Anatomic Considerations

The typical liver transplant is connected to its host via five anastomoses (Fig. 182-6). The vessels are connected first, allowing organ reperfusion. The biliary system is then reconstructed and often stented with a T tube to prevent stenosis. In the early post-transplant period, T tubes may be replaced if restenosis develops. The most common vascular complication is hepatic artery thrombosis, which most commonly occurs early in the post-transplant period. Severe graft dysfunction is invariably and mortality approaches 75%.
**Rejection**

Liver transplant rejection is the norm despite immunosuppressive therapy. Rejection often begins 1 or 2 weeks after surgery, with fever, right upper quadrant pain, and elevated bilirubin and transaminases. Leukocytosis may occur but is nonspecific. Related conditions that simulate graft rejection are mechanical biliary obstruction, primary nonfunctioning graft, ischemia from thrombosis of vascular anastomoses, viral infections, drug toxicity, and recurrent primary disease.43-46

As soon as transplant rejection is suspected, treatment with high-dose methylprednisolone should begin. Hospitalization is routine. If this fails to diminish the rejection episode, OKT3 monoclonal antibodies are again used in addition to polyclonal antilymphocyte globulin.43

**Infection**

After the first postoperative month, opportunistic infections replace the common postsurgical complications. Viral (CMV and HSV), fungal (Aspergillus, Candida, and Cryptococcus), protozoan (Pneumocystis and Toxoplasma), and unusual bacterial (Nocardia, Legionella, and Listeria) infections occur. In addition, ascending cholangitis due to colonization of biliary stents with staphylococcal species, enterococci, and gram-negative organisms is common. Subsequent injury to the graft during biopsy or cholangiogram can cause cholangitis or liver abscess.

**Kidney (Renal) Transplant**

With survival rates of 96% at 1 year and 91% at 3 years, renal transplants are highly successful.28 Injury of the transplanted kidney is rare, despite its location in the retroperitoneal area of the anterior pelvis, where it may be at risk from direct blows as well as seat belt injuries.27

**Rejection**

Early kidney transplant rejection is mediated through T lymphocytes against antigen donor tissues, including cytotoxic CD8 and CD4 cells. In addition, B lymphocytes, natural killer cells, and macrophages infiltrate the foreign tissues. The B lymphocytes manufacture specific antibodies, which results in microvascular lesions impairing perfusion.

Chronic transplant rejection occurs after several years of adequate function and is a result of nephrosclerosis. This process involves proliferation of the vascular intima of renal vessels with marked decrease in the lumen size. Systemic...
hypothesis ensues as the graft fails from ischemia, with resultant tubular and glomerular atrophy.

With cadaveric kidney transplants, histocompatibility differences are almost universal and routinely require long-term immunosuppressive therapy. This is accomplished with a combination of azathioprine, prednisone, and cyclosporine. On diagnosis of acute rejection, high-dose methylprednisolone (500–1000 mg) is begun daily and continued for 3 days. After 6 to 12 months, many patients only need lower doses (10–20 mg/day). 47-48

Clinically, renal graft rejection presents as fever, swelling and tenderness over the allograft, and decreased urine output. A subtle rise in serum creatinine should prompt great concern. Renal ultrasound should be performed to rule out obstruction, abscess, vascular thrombosis, and perirenal collections of blood, pus, or lymph. 48 Early consultation with the nephrologist is prudent.

Lung Transplant

The lung may be transplanted alone or in combination with the heart, with 1-year survival rates of 76% and 56%, respectively. 24 Lung transplants are usually done unilaterally, except for cystic fibrosis. Unequal lung sounds are to be expected. There is no published experience with lung injury following transplant. Comparison of chest radiography with preinjury studies is critical in the evaluation of trauma. Chest tube placement on the transplanted side may be difficult because of adhesions and loculations. 27

Rejection

Although still rare, lung transplantation is increasing in frequency; more than 800 are performed annually in the United States. 24 Most patients develop early rejection, and 25 to 40% have chronic rejection. An episode of acute rejection can occur as early as a few days after transplantation or as late as several years. Clinically, the patient presents with cough, dyspnea, and fever. Rales and rhonchi are heard, with deterioration in oxygenation and pulmonary function. Early rejection is often accompanied by infiltrates on chest radiograph. When rejection occurs more than a month after transplantation, 75% of radiographs are normal or unchanged. The diagnosis of rejection is made by transbronchial biopsy showing lymphocytic infiltration. 16,49-51

Suspected episodes of acute rejection are treated with high-dose methylprednisolone (500–1000 mg/day). This is successful in reversing most episodes, but OKT3 can be used in refractory cases. 50

Chronic lung transplant rejection is a leading cause of late morbidity and mortality. Antecedent acute rejection and CMV pneumonia are risk factors. Pathologically, vascular sclerosis and progressive limitation to airflow occur from obliteratorive bronchiolitis. Rejection can occur several years after transplantation, but the mean time to onset is 8 to 12 months. Clinically, this rejection mimics an upper respiratory infection or bronchitis. If dyspnea is a component of the presenting complaint, a search for transplant rejection should be initiated. 49,52

Chronic rejection is treated with high-dose methylprednisolone (500–1000 mg/day), with the first dose begun in the ED. Antilymphocyte antibodies are used as well, but relapse of the rejection episode is common.

Infection

Transplanted lungs are highly susceptible to pneumonia because they can be colonized by bacteria during the ventilator stage of the brain-dead donor. After transplant, diminished mucociliary clearance, decreased cough reflex due to denervation, and defective function of alveolar macrophages are present. The most common infections are caused by gram-negative bacteria such as Pseudomonas and Staphylococcus aureus. Antibiotic therapy should be aggressively directed toward any pathogenic bacteria cultured from the tracheobronchial tree. Community-acquired pneumonia must be considered as well. Pneumocystis pneumonia is uncommon because of routine prophylaxis with TMP-SMX. 1,50

CMV pneumonia is the most common opportunistic pulmonary infection after lung transplantation. Patients are at highest risk between 3 weeks and 4 months. Clinically, CMV infection closely resembles transplant rejection. Tissue biopsy and viral culture are required to differentiate the two entities. Treatment with ganciclovir is effective. Colonization by Candida is common, but not invasive disease. Aspergillus provides the most significant fungal threat to the transplanted lung. Reactivation of tuberculosis is rare. 50,51

Pancreas Transplant

The pancreas may be transplanted singly or in combination with a kidney. This is typically secondary to diabetes. Pancreatic transplants have a high complication rate, with 1-year graft survival rates as low as 72%. Because the exocrine functions of the allograft pancreas are usually drained into the bladder, genitourinary complaints are also common. Duodenocystostomy fistula may form in the early post-transplant period. The clinical findings are abdominal pain, tenderness, hyperamylasemia, leukocytosis, and elevated serum creatinine. Other types of pancreatic transplant complications include urinary tract infections, hematuria, reflux pancreatitis, rejection, and pancreatic graft thrombosis. 53-55

Anatomic considerations are important when these patients suffer major trauma because pancreas transplants are placed in the pelvis overlying the iliac vessels. 27 Exocrine secretions are drained into the bladder for excretion, and patients have a chronic non-anion gap acidosis through loss of bicarbonate into the bladder. This should not be confused with lactic acidosis. These trauma patients should not require exogenous insulin, unless the graft is injured. Positive amylase on peritoneal lavage (CT is recommended if the patient is stable) can result from either native organ or graft trauma or from a ruptured bladder. CT scanning should be done with rectal contrast, in addition to IV and oral, to better define the native and transplanted pelvic organs. 27

Islet cell transplantation is under investigation as a treatment for diabetes mellitus. If successful, this procedure may negate the need for future solid organ pancreas transplants and the resultant complications.

PSYCHOLOGICAL ASPECTS OF ORGAN TRANSPLANTATION

The psychological issues that surface while under consideration for or after reception of an organ transplant impact many patients. Organ transplantation is no longer considered experimental, and it is a common therapeutic option for end-stage organ failure. Strong emotions naturally occur and should be acknowledged in donors, recipients, and transplanters.

Transplant programs widely employ psychosocial selection criteria. Generally, the cardiac programs have the most stringent criteria. The side effects of lifelong immune suppression or steroid withdrawal can include anxiety, depression, and insomnia. On the other hand, successful transplantation often improves psychological well-being. Transplant social workers
can provide awareness of and access to the social network that should surround each transplant recipient. Long-term compliance with all aspects of treatment will minimize graft rejection.56

■ DISPOSITION
Patients with solid organ transplants presenting to the ED have a much higher than average rate of hospitalization.28,46 The insidious nature of the diseases affecting this immunosuppressed population mandates a thorough approach to evaluation. If organ rejection, infection, or drug toxicity is evident, local transplantation specialists should be consulted. Physicians without significant transplant experience should contact the patient’s transplant center to obtain consultation and coordinate follow-up care. Patients who are discharged require careful instructions and close follow-up.

Alcohol-Related Disease

John T. Finnell and David B. McMicken

PERSPECTIVE

Epidemiology

The disastrous effects and widespread incidence of alcoholism are well known to the emergency physician. Motor vehicle collisions, drowning, suicides, homicides, divorce, violent crime, child abuse, unemployment, and disruption of the family are often either directly or indirectly associated with excessive alcohol consumption. The tragic effects of alcohol not only affect the individual drinker but also have far-reaching implications for the family, community, and workplace. There are an estimated 68.8 million emergency department (ED) visits, with a rate of 28.7 per 1000 U.S. population. The 5-year mortality rate among alcohol-intoxicated ED patients was 2.4 times that of a comparison group in one study.

A simple, rapid, and respectful screening test for alcoholism is the four CAGE questions: Have you ever felt

- The need to Cut down on your drinking?
- Annoyed by criticism of your drinking?
- Guilty about your drinking?
- The need to drink an Eye opener in the morning?

Positive answers to two or more of these questions are sufficient to identify individuals who require more intensive evaluation. Also, a positive answer to the question, “Have you ever had a drinking problem?” plus evidence of alcohol consumption in the previous 24 hours provides greater than 90% sensitivity and specificity as a screening tool for identifying alcoholism.

Alcohol is the most common recreational drug taken by Americans, and per capita consumption is increasing. Alcoholism affects approximately 12% of individuals in the United States during a lifetime. Alcoholism permeates all levels of society and is the leading cause of preventable mortality and morbidity, with a cost to the nation estimated to be greater than $185 billion annually. An estimated 18 million alcoholics live in the United States. With more than 100,000 alcohol-related deaths occurring each year, alcohol is the third leading cause of preventable death in the United States.

Definition and Natural History

A precise definition of alcoholism is difficult. A proposed definition encompassing the features of alcoholism is “a primary chronic disease with genetic, psychosocial, and environmental factors influencing its development and manifestations.” The disease is often progressive and fatal. It is characterized by impaired control over drinking, preoccupation with and use of alcohol despite adverse consequences, and distortions in thinking, most notably denial. Each of these symptoms may be periodic or continuous.

Alcoholism is present when drinking adversely affects an individual’s physical health, ability to function in society, or interpersonal relationships. Certainly, the patient who has a dependence on ethanol can be labeled “alcoholic.”

Hazardous or “at-risk” drinking is defined by the National Institute on Alcohol Abuse and Alcoholism as follows:

Men: more than 14 drinks per week or more than 4 drinks per occasion
Women: more than 7 drinks per week or more than 3 drinks per occasion
Age older than 65: more than 7 drinks per week or more than 1 drink per occasion

Harmful drinkers present with negative consequences related to alcohol.

The cause of alcoholism is not completely understood but appears to be a complex interaction between biologic and environmental factors. Genetic variability of enzymes for alcohol metabolism may be a risk factor supported by family, twin, and adoption studies. A large study, entitled the Collaborative Studies on Genetics of Alcoholism (COGA) is now identifying additional gene loci.

The natural history of alcoholism is variable, and it may appear in any patient despite age or social status. The age of onset of alcoholism continues to decrease. Up to 6% of high school seniors drink daily, and it is not unusual to see children younger than 16 years of age who have already graduated from school seniors drink daily, and it is not unusual to see children younger than 16 years of age who have already graduated from an alcohol detoxification program. Many individuals also begin drinking heavily after age 60.

The fourth edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV) has two categories for substance disorders that include alcohol abuse. It lists criteria for substance abuse and substance dependence. The chronic substance abuse of alcohol eventually leads to acquired tolerance, a condition in which increasingly larger doses of alcohol are required for the same effect. An inborn tolerance also exists. There is a wide variance in abnormal behavior independent of the patient’s drinking experience.

Continued alcohol abuse progresses to substance dependence, defined in DSM-IV as a maladaptive pattern of substance use leading to clinically significant impairment, as manifested by three or more of the following occurring in the same 12-month period:
1. Physiologic dependence, as evidenced by tolerance or withdrawal
2. Alcohol taken in larger amounts or over a longer period than was intended
3. Persistent desire or unsuccessful efforts to control alcohol consumption
4. Great amount of time spent in activities necessary to obtain alcohol or recover from its effects
5. Important social, occupational, or recreational activities forsaken for sustained alcohol use
6. Continued alcohol use despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by alcohol

**PRINCIPLES OF DISEASE: METABOLISM OF ALCOHOL**

Ethanol is rapidly absorbed from the stomach and small intestine. It is distributed uniformly to all organ systems, including the placenta. The oxidation of alcohol is a complex process involving three enzyme systems, all contained in the hepatocyte. The pharmacokinetic properties of alcohol metabolism are well-known. The class I alcohol dehydrogenase (ADH) isoenzymes, ADH1A, ADH1B, and ADH1C, oxidize ethanol. ADH1B and ADH1C have polymorphic properties with distinct kinetic properties. At the ADH3 locus, two alleles allow for pharmacokinetic differences of 2.5-fold in maximum velocity of ethanol oxidation.11

\[
\text{Ethanol} \xrightarrow{\text{Alcohol dehydrogenase}} \text{Acetaldehyde} \xrightarrow{\text{Alcohol dehydrogenase}} \text{Acetyl coenzyme A} \xrightarrow{\text{Citric acid cycle}} \text{CO}_2 + \text{H}_2\text{O}
\]

An alternative pathway, the *microsomal ethanol-oxidizing system* (MEOS), can be induced by chronic alcohol exposure. The primary component of MEOS is the molecule cytochrome P450, which exists in several variants. The variant most important for alcohol metabolism is cytochrome P450 2E1 (CYP2E1). Many effects of alcoholism are produced by the toxic by-products (hydrogen and acetaldehyde), the acceleration of metabolism of other drugs, and activation of hepatotoxic compounds by these metabolic pathways.

Although the liver is the major site of ethanol metabolism, other tissues contribute to its metabolism. ADH is found in the gastric mucosa, but the gastric metabolism of alcohol is decreased in women and those of Asian decent. This increased bioavailability of ethanol or decreased first-pass metabolism may explain the enhanced vulnerability of women to acute and chronic complications of alcohol.

Studies have shown two alcohol elimination curves. The alcohol elimination rate approximates zero-order kinetics (constant rate) for lower ethanol levels and first-order kinetics (the amount of drug removed over time is proportional to the concentration of the drug) for higher levels, especially in chronic alcoholics. The MEOS pathway may account for the increased elimination rate at higher blood levels.

The absorption and elimination rates of alcohol vary by individual and depend on many factors: diet, gender, body weight and habitus, speed of consumption, gastric motility, the presence of food in the stomach, smoking history, age, whether the person is a chronic alcohol consumer with enzyme induction and high-activity MEOS, advanced cirrhosis, the presence of ascites, and the state of nourishment.12 There is enormous variation among patients in the rate of disappearance of ethanol from the blood, ranging from 9 to 36 mg/dL/hr in published data.

**DIFFERENTIAL CONSIDERATIONS**

Acute alcohol intoxication is a diagnosis of exclusion. Before assuming that a patient’s behavior is caused only by alcohol, other conditions should be considered. Hypoglycemia, hypoxia, carbon dioxide narcosis, mixed alcohol-drug overdose, ethylene glycol or methanol poisoning, hepatic encephalopathy, psychosis, severe vertigo, and psychomotor seizures can manifest in a manner similar to ethanol intoxication. The possibility of occult head trauma and the presence of associated metabolic disorders should be considered after alcohol intoxication has been established. Adequate history from paramedics and family, repeated physical examinations by the same clinician, and diagnostic adjuncts can help resolve this dilemma.

**MANAGEMENT**

Comatose or stuporuous patients need to have their airway and ventilation evaluated, with endotracheal intubation performed as necessary. Gastric lavage and activated charcoal are of little

*These effects are for the occasional drinker. Chronic drinkers can function at much higher alcohol concentrations because of tolerance. On the other hand, patients may become comatose with low levels of alcohol in mixed alcohol-drug overdose.

Although the clearance rate may be as high as 36 mg/dL/hr in some chronic drinkers, 20 mg/dL/hr is a reasonable rate to assume in a typical intoxicated ED patient. This holds true for adults, adolescents, and children. In the unusual circumstance that an accurate prediction of the rate of clearance is required, a second measurement should be obtained several hours after the initial value.13

Physiologic effects vary directly with the blood alcohol (Table 183-1). Diminished fine motor control and impaired judgment appear with alcohol concentrations as low as 20 mg/dL (0.02 %), but wide individual variability exists. Chronic alcoholics can exhibit impressive tolerance. The blood alcohol concentration (BAC) of a person cannot be accurately determined without quantitative testing. More than 50% of the adult population are obviously intoxicated with a level of 150 mg/dL (0.15 %). As the ethanol level rises, the patient’s level of consciousness declines, eventually ending in coma. Death is caused by aspiration or respiratory depression.

In most states, the legal level of intoxication while driving is 80 mg/dL (0.08 %). Many states now allow administrative driver’s license revocation at BACs as low as 20 mg/dL (0.02 %). There is not an illegal BAC for activities other than driving.

Alcohol via passive diffusion will be present anywhere there is water in the body. Hence, expired breath alcohol or saliva can be used to obtain a reliable approximation of BAC in a cooperative patient. This value can be used as a rapid screen for alcohol intoxication.14,15 The breath alcohol level can be falsely low with uncooperative patients.
value in ethanol overdose because of the rapid absorption of alcohol but may be appropriate in a suspected mixed drug-alcohol overdose.

Ethanol is similar to general anesthetics that act on the lipid moiety of cell membranes. Because there are no specialized receptors for alcohol, a specific antagonist does not exist.

Thiamine (100 mg intravenously [IV]) to prevent or treat Wernicke-Korsakoff syndrome, glucose (dextrose, 25–50 g IV) for hypoglycemia, and naloxone (0.8 mg IV) for possible opioid ingestion are considered in comatose patients. Whenever possible, hypoglycemia should be documented before the empiric administration of glucose. With the airway maintained and respirations supported, the patient’s liver eventually metabolizes the alcohol, and the patient should recover.

Glucose (dextrose, 25 g IV) produces a dramatic response in alcohol-induced hypoglycemic patients. Unlike hypoglycemia of other causes, alcohol-induced hypoglycemia may be unresponsive to glucagon because of depleted liver glycogen stores. Although Wernicke’s encephalopathy is a medical emergency, alcohol-induced hypoglycemia is a much more common condition with serious and permanent morbidity if left untreated. Therefore, thiamine can be given in a timely fashion, but glucose therapy should not be delayed.16

Intoxicated patients require evaluation and treatment in the ED regardless of their obstreperous nature. Inappropriate discharge and failure to diagnose are two common areas of liability when treating the alcohol-dependent patient. The theoretical liability for detention by reasonable restraint is less than the potential liability for injury sustained by the alcohol-dependent patient or an innocent bystander after premature discharge. Discharge (after excluding significant abnormal laboratory values or suspected head injury) can be considered when a patient is clinically sober and able to dress, walk, and function independently. In ideal circumstances, a concerned, sober adult is available and willing to take responsibility for and remain with the patient for the next 24 to 48 hours.

ALCOHOL WITHDRAWAL SYNDROME

Principles of Disease

The neurophysiology of alcohol withdrawal is complex and not fully understood. Chronic alcohol consumption has a depressant effect on the central nervous system (CNS). The hallmark of alcohol withdrawal is CNS excitation with increased cerebrospinal fluid (CSF), plasma, and urinary catecholamine levels.

Chronic alcohol consumption affects central adrenergic alpha-receptors, glutamate, central adrenergic beta-receptors, the inhibitory neurotransmitter γ-aminobutyric acid (GABA), and dopamine turnover. The effectiveness of lofexidine and clonidine (α2-adrenergic agonists), propranolol and atenolol (beta-blockers), haloperidol (dopamine blocker), and benzodiazepines and propofol (GABA transmission blockers) in suppressing the signs and symptoms of alcohol withdrawal supports this concept.17,18

Differential Considerations

Alcohol withdrawal syndrome can initially be confused with acute schizophrenia, encephalitis, drug-induced psychosis, thyrotoxicosis, anticholinergic poisoning, and withdrawal from other sedative-hypnotic–type drugs. It may be difficult to differentiate between alcohol withdrawal and alcohol-induced hypoglycemia.

Acute schizophrenia usually has its onset in adolescence or early adulthood. Manifestations include multiple bizarre delusions and a flat affect with the patient otherwise oriented. The patient in alcohol withdrawal is usually older (20s or 30s), hyperactive, and often disoriented. An important distinction: the schizophrenic patient will typically describe auditory hallucinations, whereas the alcoholic patient in withdrawal will more often describe visual hallucinations.

Encephalitis can produce headache, confusion, fever, and seizures. Thyrotoxicosis is more common in women, and its features include irritability, insomnia, tremor, weight loss despite a good appetite, palpitations, and frequent stools. Physical examination may reveal lid lag, tachycardia, and a bruit over the thyroid. No relationship exists between the onset of encephalitis or thyrotoxicosis and alcohol consumption. Anticholinergic poisoning can occur with several different drugs or plant ingestion. The classic clinical picture is a patient with dry mouth, dry eyes, dry skin, hypoa analytic bowel sounds, urinary retention, and delirium. Amphetamine and cocaine intoxications produce anorexia, insomnia, and physical signs of CNS sympathetic overactivity.

In opioid withdrawal, patients complain of abdominal pain and diarrhea, the mental status is usually normal, the patient is afebrile, and seizures are uncommon (with the exception of meperidine). In contrast, patients with major alcohol withdrawal are usually disoriented and febrile and may have seizures.

Signs of alcohol withdrawal usually begin 6 to 24 hours after a decrease in the patient’s usual intake of alcohol. If patients manifest withdrawal 3 days or more after their last drink, drugs with a longer half-life should be considered. The barbiturate and benzodiazepine withdrawal syndromes usually progress more slowly, with a higher frequency of seizures later (7 vs. 2 days), and status epilepticus is more common than with alcohol withdrawal.

Clinical Features

Isbell and colleagues’ classic 1955 study confirmed the relationship between alcohol and the withdrawal syndrome.19 They documented that the severity of signs and symptoms depends on both the dose and the duration of ethanol consumption. The withdrawal syndrome may occur any time after the blood alcohol level starts to fall. Therefore, only a reduction, not the abrupt cessation, of ethanol intake may result in withdrawal.

The withdrawal syndrome usually develops 6 to 24 hours after the reduction of ethanol intake and lasts 2 to 7 days. The alcohol withdrawal state ranges from mild withdrawal with insomnia and irritability to major withdrawal with diaphoresis, fever, disorientation, and hallucinations.

Minor alcohol withdrawal occurs as early as 6 hours and usually peaks at 24 to 36 hours after cessation of or significant decrease in alcohol intake. It is characterized by mild autonomic hyperactivity: nausea, anorexia, coarse tremor, tachycardia, hypertension, hyper-reflexia, sleep disturbances (e.g., insomnia and vivid dreams), and anxiety.20

Major alcohol withdrawal occurs after more than 24 hours and usually peaks at 50 hours but occasionally takes up to 5 days to manifest after the decline or termination of drinking. The syndrome is characterized by pronounced anxiety, insomnia, irritability, tremor, anorexia, tachycardia, hyper-reflexia, hypertension, fever, decreased seizure threshold, auditory and visual hallucinations, and, finally, delirium.21

Delirium tremens is the extreme end of the spectrum and consists of gross tremor, frightening visual hallucinations, profound confusion, agitation, and a hyperadrenergic syndrome characterized by a temperature greater than 101°F, a blood pressure greater than 140/90 mm Hg, and tachycardia. It seldom appears before the third postabstinence day. Only 5% of patients hospitalized for alcohol withdrawal develop
delirium tremens. Other causes of delirium to be considered in the alcoholic patient include sepsis, meningitis, hypoxia, hypoglycemia, hepatic failure, and intracranial bleeding. True delirium tremens is rare and is not synonymous with alcohol withdrawal.

Management

Out-of-Hospital Care

The alcoholic-dependent patient in withdrawal may also have a mixed alcohol-drug ingestion, occult head trauma, or cervical spine injury. Patients who are unable to sit without assistance or have an altered mental status require IV access. Naloxone (0.8 mg) and glucose (dextrose, 25 g) may be given in an IV bolus. Rapid blood glucose testing is preferable, but glucose may be given for altered mental status if this testing is not readily available. Thiamine should be given as soon as possible after glucose. The airway should be maintained and respirations supported. Emergency medical service personnel should monitor the patient’s vital signs and neurologic status. The cervical spine should be immobilized if trauma is suspected. It is usually best to withhold additional treatment until the patient can be evaluated in the ED. Emergency medical service personnel should be alert for other medical disorders that accompany alcoholism, such as pneumonia, sepsis, gastrointestinal bleeding, pancreatitis, hepatic failure, hypoglycemia, and intracranial hemorrhage.

Hospital Care

Initial Assessment. Family, friends, bystanders, or paramedics may give more reliable historical data than the patient. Accurate vital signs are essential. This may require a rectal temperature. Hyperthermia, hypothermia, tachypnea, or tachycardia may suggest serious disorders that often accompany the alcohol-dependent patient. These disorders should be considered during this first assessment.

A rapid, thorough examination should be done with attention to the level of consciousness, signs of hepatic failure, or coagulopathy. Signs of trauma are sought, such as subcutaneous emphysema, ecchymosis, subconjunctival hemorrhage, hemotympanum, Battle’s sign, or palpation for fractures. The neurologic examination should search for focal findings, including central facial nerve palsy, hemiparesis, asymmetry of reflexes, or asymmetry of pupillary response.

Treatment Plan. The alcohol withdrawal syndrome should be promptly recognized and treated. Treatment is necessary (1) to provide relief from anxiety and hallucinations; (2) to halt progression to major withdrawal and withdrawal seizures; (3) to allow detection of a treatable primary psychiatric illness; (4) to prepare the patient for long-term alcohol abstinence with the lowest risk of new drug dependence; and (5) to calm the patient and allow adequate examination for the detection of medical illnesses that typically accompany alcoholism, such as gastritis, dehydration, pancreatitis, pneumonia, electrolyte disorders, and hepatitis.

In combination with appropriate chemical sedation, detention by reasonable restraint may be an option to prevent potential injury that patients may inflict on themselves or the hospital staff. Appropriate restraints are preferable to allowing decision-challenged patients to sign an “against medical advice” form and be discharged.

Pharmacologic Intervention. Patients suffering from alcohol withdrawal should receive pharmacologic intervention along with supportive care. The ideal drug for alcohol withdrawal would have a rapid onset, a wide margin of safety, a metabolism not dependent on liver function, and limited abuse potential. Although no one drug class fits all these requirements, benzodiazepines are clearly the mainstay of treatment.

Benzodiazepines. The benzodiazepines have superior anticonvulsant activity, have the least respiratory and cardiac depressive effect of all the CNS depressants, and can be given parenterally in the uncooperative patient. By interacting with receptors linked to the GABA-associated chloride ion channel, benzodiazepines substitute for the withdrawal of the GABA-potentiating effect of alcohol and abate withdrawal signs and symptoms.

Numerous benzodiazepines have been studied. No evidence of clear superiority of any one benzodiazepine exists. Lorazepam has good bioavailability with oral, intramuscular (IM), and IV routes. It is rapidly and completely absorbed from IM sites in agitated patients with no IV access. Lorazepam’s half-life is intermediate (7–14 hours), and it reaches a steady state in 36 to 48 hours without active metabolites. Excessive sedation, confusion, and ataxia are potential complications of all benzodiazepines with prolonged half-lives. Lorazepam is metabolized (conjugated) in the liver, yielding inactive products. Although lorazepam’s half-life increases in patients with cirrhosis or liver failure, it is much less than the increase with chloralazine. Lorazepam’s elimination is only minimally altered in patients with renal failure and in the elderly.

Lorazepam may be given IV in a dose of 1 to 4 mg, depending on the severity of the withdrawal. Dosing can be repeated at 5- to 15-minute intervals for patients in severe withdrawal. An IM dose of 1 to 4 mg can be used every 30 to 60 minutes until calm, then every hour as needed for light somnolence. The oral schedule for moderate withdrawal is 6 mg/day in three divided doses, tapering the amount by 1 or 2 mg/day over 4 to 6 days. Diazepam can be given in a dose of 5 mg IV every 5 to 10 minutes (2.5 mg/min) in major withdrawal until the patient is calm. The dose can be repeated in 5 to 10 minutes. If the second dose of 5 mg is not working, consider 10 mg for the third and fourth doses every 5 to 10 minutes. If this is not effective, consider 20 mg for the fifth and subsequent doses until adequate sedation is obtained. Because of erratic absorption, diazepam should not be given IM.

The dosage of benzodiazepines required for alcohol withdrawal is highly variable. Practically, the dose is titrated to the patient’s agitation. Massive IV drug doses have been required in patients with delirium tremens, including a recorded 2640 mg of diazepam and 35 mg of haloperidol over 48 hours, 75 mg of midazolam in 1 hour, and 2850 mg of midazolam over 5 days.

Butyrophenones. Haloperidol, a dopamine antagonist, can be considered in patients with major alcohol withdrawal or delirium tremens not responding to IV benzodiazepines. Haloperidol is more potent than chlorpromazine, has lower anticholinergic properties, and has less propensity to cause cardiovascular side effects or lower the seizure threshold. Haloperidol has little effect on myocardial function or respiratory drive, and its safety and efficacy by the IV, IM, or oral route in the ED have been established. Haloperidol has no anticonvulsant properties, however extrapyramidal effects may be seen. In 2008, Ortho-McNeil placed a black box warning on haloperidol for elderly patients with dementia-related psychosis. Elderly patients with dementia-related psychosis treated with antipsychotic drugs such as haloperidol have 1.6 to 1.7 times the risk of death compared with placebo-treated patients. Caution should be used in patients who may be susceptible to a prolonged QTc. Droperidol has similar effects as haloperidol. In 2001, the Food and Drug Administration issued a black box warning regarding QTc prolongation and torsades de pointes following droperidol use; nevertheless, droperidol remains a
Differential Diagnosis of Alcohol-Related Seizures

Withdrawal (alcohol or drugs)
Exacerbation of idiopathic or post-traumatic seizures
Acute intoxication (amphetamines, anticholinergics, cocaine, isoniazid, organophosphates, phenothiazines, tricyclic antidepressants, salicylates, lithium)
Metabolic (hypoglycemia, hyponatremia, hypernatremia, hypocalcemia, hepatic failure)
Infectious (meningitis, encephalitis, brain abscess)
Trauma (intracranial hemorrhage)
Cerebrovascular accident
Sleep deprivation
Noncompliance with anticonvulsants

Emergency Department and Outpatient Approaches

Rapid, aggressive control of alcohol withdrawal is crucial. The cornerstone of treatment is a benzodiazepine. Lorazepam is preferable because of its previously discussed qualities.

An initial test dose of lorazepam may be given IV in a dose of 1 to 4 mg, depending on the severity of the withdrawal. Dosing can be repeated at 5-15-minute intervals for patients in severe withdrawal. An IM dose of 1 to 4 mg can be used every 30 to 60 minutes until a patient is calm and then every hour as needed for light somnolence. Patients remain under observation or are admitted until the manifestations of withdrawal do not progress after the effects of the benzodiazepine have dissipated.

Outpatient treatment consists of lorazepam, 1 or 2 mg three times a day in a tapering dose for 3 to 6 days; chlordiazepoxide, 25 to 100 mg three times a day in a tapering dose for 3 to 6 days; or diazepam, 30 mg once a day tapered over 5 days depending on the severity of symptoms. Adequate diet, abstinence, and participation in a rehabilitation program in the community are also desirable. Any patient requiring 300 mg of chlordiazepoxide or 60 mg of diazepam per day to control withdrawal should be considered for admission. Patients with major alcohol withdrawal (disorientation, hallucinations, diaphoresis, or fever) are admitted. Doses approximately equivalent to 100 mg of chlordiazepoxide are 20 mg of diazepam and 5 mg of lorazepam.

Adjunctive Therapy

Patients being treated for major alcohol withdrawal should receive thiamine (100 mg IV) and magnesium (2 g IV). Although magnesium sulfate does not decrease the severity of withdrawal symptoms, the incidence of delirium, or seizures, it carries no significant risk (with adequate renal function) or cost. In the nonacute setting, oral magnesium supplementation in chronic alcoholics improves liver function tests, electrolyte balance, and muscle strength. Multivitamin preparations may be considered for chronic malnutrition. Although their clinical benefit is not proved, they carry no significant risk or cost.

If present, volume depletion can be corrected with normal saline. Reversal of electrolyte and metabolic disorders (hypomagnesemia, hypophosphatemia, hypokalemia, and acidosis) benefits the patient, but it does little to abate the withdrawal syndrome.

Phenothiazines are contraindicated because they can produce hypotension, lower seizure threshold, disturb central temperature regulation, and cause extrapyramidal effects in the dosages required to calm patients in alcohol withdrawal.

Alcohol Withdrawal Seizures

Descriptions of alcohol withdrawal seizures (AWSs) were based on data collected by Victor and Brausch on 241 alcohol abusers with seizures or an alcohol-related illness complicated by seizures. Seizures occurred 6 to 48 hours after the cessation of drinking. Ninety percent had one to six generalized tonic-clonic seizures. Sixty percent experienced multiple seizures within a 6-hour period. However, data suggest seizure recurrence can be reduced to 3% with lorazepam administration following the initial seizure. The incidence of partial seizures, common with post-traumatic epilepsy, is increased in alcohol withdrawal. Regardless, first-time seizures and partial seizures warrant an evaluation for intracranial pathology.

The term alcohol withdrawal seizure is reserved for seizures with the characteristics described by Victor and Brausch. The term alcohol-related seizure (ARS) is used to refer to all seizures in the aggregate associated with alcohol use, including this subset of AWS.

Management

After ensuring airway, breathing, and circulation (ABC), treatment should start by quickly establishing intravenous access.
If the patient has altered mental status, thiamine, magnesium, dextrose, and naloxone should be considered. An empirical glucose bolus should not be used if an accurate determination of blood glucose is quickly possible.  

Although magnesium administration does not decrease the severity of withdrawal symptoms, the incidence of delirium, or seizures, it carries no significant risk or cost. In the nonacute setting, oral magnesium supplementation in chronic alcoholics improves liver function tests, electrolyte balance, and muscle strength. Multivitamin preparations may be considered for the patient's IV fluid for chronic malnutrition. Their clinical benefit is not proven. 

Treatment with 2 mg of lorazepam IV reduces the risk of recurrent seizure in chronic alcoholics from 3 to 24%. It is often difficult to rule out a CNS infection in alcoholics because of concomitant hyperthermia, serum leukocytosis, and CSF pleocytosis. Although fever may suggest meningitis, it may be found in intracranial hemorrhage, brain abscess, alcohol withdrawal, toxic ingestions, and infections outside the CNS. Temperature can rise as a result of tonic-clonic seizure. Although there were few infections found in a retrospective series of 140 patients presenting with ARS, if CSF infection is a possibility, IV antibiotics should be started, blood cultures obtained, and a lumbar puncture (LP) undertaken. An LP may be delayed until a space-occupying lesion is ruled out with computed tomography (CT) scanning, but antibiotics should not be delayed if meningitis is a possibility.

**Patients Presenting with a Normal Neurologic Exam**

**New-Onset Alcohol-Related Seizures**

Patients with new-onset ARS should be thoroughly evaluated. This includes alcoholics who claim to have had seizures but for whom no documentation or an appropriate workup is available. Metabolic disorders, toxic ingestion, infection, and structural abnormalities should be considered. Laboratory and radiographic testing including electrolytes, blood urea nitrogen, creatinine, glucose, anticonvulsant levels, and brain CT scan may be necessary. Of 259 patients presenting with their first ARS, clinical management was changed in 3.9% based on head CT results. 

If the initial physical exam, imaging studies, and laboratory tests are within normal limits, patients who remain seizure free and symptom free with no sign of withdrawal after 4 to 6 hours of observation may be discharged. These criteria may be difficult to meet; therefore, admission may be considered. 

It may be unclear whether the patient has had a pure AWS or a new-onset seizure disorder in the setting of alcohol ingestion. Long-term treatment with antiepileptic drugs (AEDs) is not necessary in unprovoked new-onset seizures that have resolved or when a clear cause of seizures, such as alcohol consumption, can be identified. Optimal outpatient treatment includes follow-up and referral to a detoxification/rehabilitation program. Ideally, the help of a concerned family member or friend, who is not a drinking partner, is helpful.

**Seizures in the Alert Patient with a History of Seizures during Prior Withdrawal**

The risk of seizure increases significantly in alcoholic patients with manifestations of alcohol withdrawal who relate a history of AWS. Detoxification with benzodiazepines reduces AWS and should be initiated early because most AWSs occur within the first 24 hours after alcohol withdrawal. An initial dose of 2 mg of lorazepam or 5 mg of diazepam can be given intravenously. These doses frequently need to be repeated. The patient is observed for 4 to 6 hours before he or she is considered for discharge. Prescribing benzodiazepines or AEDs upon discharge carries its own hazards. Prescribing benzodiazepines (other than a short 3- to 6-day tapering dose for withdrawal) may increase the potential risk of addiction. Using AEDs, such as phenytoin, in a potentially noncompliant patient may paradoxically increase the number of seizures by having large fluctuations in blood levels. The poorly compliant alcoholic patient may do better without outpatient anticonvulsants for a concurrent seizure disorder. The ideal disposition is referral to a detoxification/rehabilitation unit.

**Alert Patient with a Seizure before or after Presentation**

The alcoholic patient with a known history of ARSs who experiences a single seizure or a short burst of seizures should be treated with benzodiazepines. These patients can usually be discharged after monitoring of neurologic status for 4 to 6 hours.

**Patients with an Abnormal Neurologic Presentation**

**New-Onset Partial Seizures**

Partial seizures are reported to account for 24 to 51% of ARS. Conversely, studies have shown that 17 to 21% of partial ARS patients have structural lesions (hematomas, tumors, vascular abnormalities, or stroke). These primary causes of partial ARS, such as prior head trauma, may be easily missed in the history taking. As a result, an emergent CT scan is indicated to evaluate new-onset partial seizures. The patient with a history of a focal ARS who has been previously evaluated does not require an emergency CT scan, provided a return to baseline occurs promptly. A patient presenting with a focal ARS with subsequent normal neuroimaging can be managed with supportive care, observation for 4 to 6 hours, and a benzodiazepine for withdrawal signs or symptoms. Appropriate follow-up should be arranged.

**Status Epilepticus**

Although fewer than 8% of ARS patients go into status epilepticus, alcohol is implicated in 15 to 24% of status epilepticus cases. Status epilepticus may also be the first presentation of ARS. The most common cause of status epilepticus is discontinuation or erratic compliance with an anticonvulsant drug regimen, followed by ARS. However, status epilepticus may arise for a variety of reasons and is often multifactorial.

Initial interventions for the alcoholic in status epilepticus include stabilization of the ABCs, administration of thiamine and glucose as indicated, and treatment with a benzodiazepine. Lorazepam and diazepam are both effective in terminating seizures in status epilepticus. Lorazepam is preferable because its anticonvulsant effect lasts several hours, whereas diazepam's anticonvulsant effect lasts only 20 to 30 minutes.

**Obtundation**

The obtunded or stuporous alcohol-dependent patient with a history of seizure activity poses a diagnostic challenge. The patient’s decreased level of consciousness (LOC) may be the result of a postictal state, occult head trauma, unrecognized...
metabolic disorder, or poisoning. The first diagnostic task is to quickly determine the possibility of hypoglycemia (diagnosed and reversed at the bedside in minutes) and the evaluation of other metabolic and toxic causes of altered mental status. Patients with an acute alteration in mental status should undergo an emergent head CT if they are not demonstrating expected and obvious improvement.

No History of Seizures, No Current Seizure

In the alcoholic patient in withdrawal who lacks a history of seizures, benzodiazepines generally have sufficient anticonvulsant activity to prevent withdrawal seizures.

Phenytoin-Anticonvulsant Conundrum

Phenytoin has no significant benefit over placebo in preventing recurrence of AWS. Considering the risks of phenytoin and because it has no demonstrated benefit in the setting of AWS, it is not indicated for the treatment of AWS. The sudden withdrawal of phenytoin may potentiate the convulsive effects of alcohol withdrawal. Withdrawal seizures may occur in epileptic patients withdrawn from phenytoin.29,53

Alcoholic patients with preexisting seizure disorders pose a dilemma when they are supposed to be taking antiepileptic drugs but their blood levels suggest noncompliance. This is especially problematic when their epileptic attacks are uncommon and appear to occur exclusively in the context of alcohol withdrawal. Some of these patients may have AWS and may have been misdiagnosed. Others may have a seizure disorder that appears to be confined to the setting of alcohol withdrawal. Such patients have demonstrated that they cannot maintain compliance with their treatment.

A patient currently taking AEDs for an antecedent seizure disorder who presents with a seizure while intoxicated falls into a different category. Such an episode could be an isolated event in a usually compliant patient without a history of chronic alcohol abuse. In this patient, a seizure in the setting of a subtherapeutic AED level may represent the consequences of noncompliance with AED or sleep deprivation versus AWS.43

• OTHER CLINICAL FEATURES AND MANAGEMENT

Cardiovascular Effects

Acute and chronic ethanol consumption can affect the mechanical function of the heart, produce dysrhythmias, and exacerbate coronary artery disease (CAD). It may alter myocardial function by direct toxic effects, associated hypertension, or indirectly by altering specific electrolytes. Acute intoxication can decrease cardiac output in both alcoholic and nonalcoholic patients with preexisting cardiac disease.53

Studies have linked moderate alcohol consumption (up to two drinks per day in men and one in women) to a protective effect from CAD. As much as 50% of the relative risk reduction of CAD can be explained by increased levels of high-density lipoprotein (HDL) and its subfractions HDL-2 and HDL-3. Genetic variations in the ADH allele may account for these changes. Low to moderate alcohol consumption decreases platelet aggregation, raises plasma levels of endogenous tissue plasminogen activator,54 and lowers insulin resistance. Experimental data suggest that alcohol may have antioxidant properties, produce effects on smooth muscles through interactions with nitric oxide, and alter plasma total homocysteine levels.55,56

Studies suggest that moderate alcohol consumption, through a reduced risk of CAD, may also protect individuals from congestive heart failure (Box 183-2).57 All of these beneficial effects are lost in heavy drinkers, in whom chronic alcoholism is associated with hypertension and congestive cardiomyopathy.

The typical patient with alcoholic cardiomyopathy is a man older than 30 years with a greater than 10-year history of chronic alcohol intake. The signs and symptoms are no different from those of low-output congestive heart failure of other causes: dyspnea, palpitations, weakness and fatigue, jugular venous distention, poor R wave progression, nonspecific electrocardiographic abnormalities, and biventricular enlargement on a chest radiograph. Echocardiography shows four-chamber enlargement with decreased left and right ventricular contractile function. Up to one third of chronic alcoholic patients have left ventricular dysfunction demonstrated by a radionuclide ventriculogram, usually coexisting with skeletal muscle disease. Women appear to be more sensitive to the toxic effects of alcohol on striated muscle and are at greater risk for cardiomyopathy and myopathy. The diagnosis is made by obtaining a history of prolonged alcohol use and excluding hypertensive, coronary, valvular, and congenital disease.

Heavy alcohol consumption (more than 2 ounces a day) has a detrimental effect on those with preexisting CAD. It can reduce exercise tolerance, induce coronary vasoconstriction, and raise heart rate and blood pressure. Additive cardiovascular effects of ethanol and nicotine contribute to dysrhythmias and sudden death in patients with CAD. In one study, nearly half the patients with alcohol withdrawal had prolongation of the QT interval. Prolonged QT can precipitate a dysrhythmia, resulting in sudden death. There is an increased incidence of sudden death among heavy drinkers regardless of concomitant CAD or smoking.

Supraventricular (usually atrial fibrillation) and ventricular (usually transitory ventricular tachycardia) dysrhythmias, labeled “holiday heart,” have been documented in alcoholic patients who have been drinking heavily. One study reported that alcohol contributes to or causes new-onset atrial fibrillation in approximately two thirds of patients younger than 65 years. Alcohol also affects cardiac function indirectly by lowering potassium and magnesium levels. Data from the Framingham Heart Study indicate that patients with lower levels of potassium and magnesium have higher rates of dysrhythmias.

Left ventricular ejection fractions improve with either abstinence or sustained decrease of alcohol consumption starting at 1 year and continue to improve over at least 4 years. Tachydysrhythmias as a result of episodic drinking commonly revert to sinus rhythm with abstinence and do not require immediate intervention if the patient is hemodynamically stable. Nevertheless, correction of electrolyte abnormalities is prudent.

Pulmonary Effects

Alcohol reduces the mobilization of alveolar macrophages and their bactericidal capacity. Their impairment is greatest in alcoholics with hepatic cirrhosis. These effects, along with aspiration, decreased airway sensitivity, concomitant smoking, and malnutrition, probably account for the increased incidence of pneumonia, particularly lobar pneumonia, among alcoholic patients.

At least 80% of alcoholics are smokers, making it difficult to distinguish between alcohol-induced and tobacco-induced injury to the lungs. The high prevalence of respiratory disease in alcoholics is largely caused by smoking. Chronic alcohol abuse has been shown to increase the risk of developing adult respiratory distress syndrome.

Alcohol induces bronchospasm in some asthmatics and increases ventricular ectopy and sleep apnea in patients with chronic obstructive pulmonary disease. Alcoholic patients with hepatic cirrhosis can have hypoxemia as a result of precapillary shunting in their lungs. Hyperventilation and respiratory alkalosis are also seen with hepatic cirrhosis. One or two drinks per day decrease the risk of pulmonary embolus and deep vein thrombosis in elderly patients.

Gastrointestinal and Hepatic Effects

Esophagus and Stomach

Alcoholic patients have a higher incidence of esophagitis, gastric cancer, and esophageal carcinoma than the general population. Acute alcohol ingestion also decreases lower esophageal sphincter pressure, delays gastric emptying, and disrupts the normal gastric mucosal barrier. Vomiting is common among drinkers. Forceful or persistent emesis can lead to a Mallory-Weiss tear or Boerhaave’s syndrome.

Gastrointestinal Bleeding

Alcohol is closely associated with gastrointestinal bleeding. Causes include Mallory-Weiss tears, esophagitis, esophageal varices, acute and chronic gastritis, thrombocytopenia, portal hypertensive gastropathy, qualitative and quantitative platelet disorders, and prolonged clotting times. Alcohol may exacerbate gastric mucosal damage when combined with nonsteroidal anti-inflammatory drugs (NSAIDs), but ethanol is not a risk factor for peptic ulcer disease. An inverse relationship exists between consumption of alcohol, particularly wine, and active Helicobacter pylori infection. Peptic ulcer disease is the most common cause of bleeding in alcoholic patients with upper gastrointestinal hemorrhage as well as in those who do not drink.

Liver

The liver is the primary site of ethanol metabolism. Hepatic damage has been recognized for centuries as the hallmark of chronic alcohol abuse. Obesity potentiates the severity of alcohol-induced liver damage. The production of cytokines such as tumor necrosis factor alpha is one of the earliest events in many types of liver injury. This cascade may trigger the production of other cytokines that together enlist inflammatory cells, kill hepatocytes, and initiate healing through fibrogenesis. There is no one test that can be used to diagnose alcoholic liver disease (ALD) reliably. However, the ratio of aspartate transaminase (AST) to alanine transaminase (ALT) greater than 1.5 suggests that alcohol is the cause of liver injury. ALD is the most common liver disorder in the Western world and, along with hepatitis C, is a leading cause of liver transplantation.

The earliest, mildest, and most common liver change seen in alcoholism is the accumulation of macrovesicular fat in the hepatocytes, predominantly involving triglycerides. Alcoholic fatty liver is usually asymptomatic, associated with mild elevations of AST and ALT. It is usually detected by the finding of hepatomegaly on physical examination or abnormalities on ultrasonography or CT but is confirmed by liver biopsy. Fatty liver is a reversible disorder if the patient can refrain from drinking.

Alcoholic Hepatitis

Alcoholic hepatitis is more serious than fatty infiltration and develops in up to 35% of heavy drinkers. These individuals usually have right upper quadrant pain, a tender enlarged liver, fever, jaundice, leukocytosis, and altered liver function tests. AST levels are usually less than 500 IU/L, and ALT levels are typically less than one half the AST levels. Alcoholic hepatitis
has a range of clinical manifestations, from mildly symptomatic hepatomegaly to fulminant hepatic failure. The severity of the disease can be estimated in the ED by a prolonged prothrombin time/international normalized ratio (INR)70 or with the use of discriminant factor.71 Model for End-Stage Liver Disease is also very helpful to predict mortality in these patients.72

Emergency department evaluation includes complete blood count, electrolytes, blood urea nitrogen, creatinine, glucose, prothrombin time/INR, liver function tests, and urinalysis. If the patient has an abnormal prothrombin time/INR and is actively bleeding, fresh frozen plasma should be started in the ED. Steroids are indicated in severe cases (encephalopathy and coagulopathy).73 Steroids are contraindicated in patients with gastrointestinal bleeding or concurrent infection. In those who are contraindicated for steroid treatment, pentoxifylline has been shown to be beneficial.74 Up to 80% of patients who continue to drink after having alcoholic hepatitis eventually develop cirrhosis.

**Alcoholic Cirrhosis**

Cirrhosis is the disruption of the normal architecture of the liver by scarring and regenerating nodules of parenchyma. Alcoholism is the most common cause of cirrhosis in the United States and is responsible for approximately 50% of all cirrhotic deaths.

Alcoholic cirrhosis usually requires 10 to 15 years of chronic drinking, often punctuated by one or more episodes of acute alcoholic hepatitis. The clinical outcome is determined by the development of complications of portal hypertension and by hepatic dysfunction. It is unknown why hepatic damage develops in some alcoholic patients and not in others exposed to identical amounts of alcohol. The disorder was originally described as “nutritional cirrhosis,” but it has been shown that alcohol, independent of malnutrition, produces liver damage. Alteration of the normal hepatic architecture by fibrosis and nodule formation may eventually lead to portal hypertension. Portal hypertension may be complicated by ascites and esophageal varices.

Hepatitis C antibodies are found in one third to one half of alcoholics with ALD, presumably from shared risk factors. Patients with ALD and hepatitis C have histologically more severe disease, shorter survival, and increased rates (by a factor of 10) of cirrhosis and liver cancer.75

No specific medical therapy exists for ALD other than abstinence, proper diet, and management of the subsequent hepatic decompensation (i.e., ascites and encephalopathy). A 60% decrease in mortality has been associated with decreasing the amount of alcohol consumed over 1 year.76 Although cirrhosis is irreversible, its progression may be halted with abstinence.

**Pancreas and Intestines**

The association of ethanol with pancreatitis is well established, but the exact pathogenesis is unclear. Hypotheses include reflux of duodenal contents and bile into the pancreatic duct, obstruction by a plug of pancreatic juice rich in proteins, and a direct toxic effect of ethanol. Ethanol abuse is associated with both acute and chronic pancreatitis.

The diagnosis of alcoholic pancreatitis can be difficult because asymptomatic alcoholics may have an elevated amylase level. In addition, up to 30% of patients with acute alcoholic pancreatitis have an amylase value within normal limits. Serum lipase rises after amylase and remains elevated longer. It appears to be a more reliable indicator of alcoholic pancreatitis, especially when more than three times normal.77 Alcohol is only one of several causes of acute pancreatitis; other causes include biliary tract disease, hypercalcemia, hypertriglyceridemia, penetrating peptic ulcer, abdominal trauma, and reactions to various drugs. Alcohol is the leading cause of chronic pancreatitis.

Diarrhea and impaired intestinal absorption are common problems of the chronic alcoholic. Alcohol increases small intestine transit time and decreases brush border enzyme activity. Thiamine, vitamin B₁₂, amino acids, folic acid, and glucose all have impaired absorption in alcoholics. Dietary deficiencies in folic acid and protein, pancreatic insufficiency, abnormal biliary secretion, and direct toxic effects of ethanol on the gastrointestinal tract all contribute to malabsorption. Abstinence and adequate nutrition reverse the diarrhea and much of the malabsorption.68

**Neurologic Effects**

**Altered Mental Status and Coma**

A potential pitfall is ascribing the cause of the patient’s altered mental state to acute intoxication without considering other conditions. Coma or an altered mental state may be caused by acute intoxication, mixed alcohol-drug overdose, postictal states, head trauma, hypoglycemia, shock from gastrointestinal bleeding or sepsis, hypothermia, hyperthermia, hepatic encephalopathy, methanol-isopropl alcohol-ethylene glycol poisoning, or Wernicke-Korsakoff syndrome.

These potentially catastrophic diagnoses are usually detected by a thorough history and physical examination, a blood alcohol level (coma is rare in patients with blood alcohol levels <200 mg/dL), and close observation (an intoxicated patient’s LOC should constantly improve over time). Patients with a less than classic presentation or course should have appropriate laboratory analysis and a head CT scan.

**Neuropathy**

A symmetrical sensorimotor polyneuropathy is common after chronic alcohol abuse, usually in the lower extremities. Its causes are thought to be a combination of nutritional deficiency with thiamine or vitamin B₁₂ deficit and a direct neurotoxic effect of alcohol. Burning pain and paresthesia are common complaints. Findings on physical examination include loss of light touch, decreased pinprick, and reduced lower extremity deep tendon reflexes. Distal muscle weakness is a late finding. The neuropathy may lead to nonhealing ulcers on the feet. Treatment of alcoholic neuropathy is abstinence, adequate diet, and thiamine. Complete recovery is rare.

“Saturday night palsy” or “honeymooner’s syndrome,” an entity caused by radial nerve compression, consists of wrist drop. The patient usually has spent the night with the arm drooped over the back of a chair, bench, or a companion, compressing the radial nerve against the humerus and producing a neurapraxia. With radial nerve neurapraxia, function usually returns after a few weeks to months.

**Wernicke-Korsakoff Syndrome**

Wernicke’s encephalopathy, a medical emergency with a mortality rate of 10 to 20%, remains a clinical diagnosis and is often unrecognized.78 Contemporary criteria require two of the following signs: (1) dietary deficiencies, (2) oculomotor abnormalities, (3) cerebellar dysfunction, and (4) either an altered mental state or mild memory impairment.79

Genetic and environmental factors may play a part in the pathogenesis of this disorder. A thiamine-dependent enzyme, transketolase, is deficient or less active in some patients with
Wernicke-Korsakoff syndrome. This may explain why the disorder develops in only a few alcoholics. People with transketolase deficiency are asymptomatic until they are stressed by thiamine deficiency. Protracted vomiting, inadequate diet, and malabsorption all contribute to thiamine deficiency in the alcoholic.79

Korsakoff psychosis or amnesic state, also called alcohol-induced persisting amnestic disorder, is a disorder with recent memory impairment, inability to learn new information or recall previously learned information, apathy, and confabulation. Although common, confabulation is not essential for the diagnosis. Age older than 40 years and many years of heavy alcohol use are risk factors. The onset may be abrupt or insidious.

Alcoholics with altered mental status should receive thiamine (100 mg IV) and either a rapid blood glucose determination or empirical dextrose (25 g IV). Treatment for Wernicke-Korsakoff syndrome consists of abstinence, adequate diet, and thiamine. The ophthalmoplegia and nystagmus usually have a good response to thiamine within hours to days. The ataxia and mental changes may take days to weeks to improve and usually have a poorer prognosis. Less than 25% of patients show any real recovery, 50% show some recovery, and the remainder show no response despite adequate thiamine replacement. Because magnesium is a cofactor for this enzyme system, serum levels should be corrected.

Patients with Wernicke’s syndrome require admission and aggressive thiamine and magnesium repletion. Recovery is variable in the Korsakoff or alcohol amnesic state.

Cerebrovascular Accident

As with CAD, many studies show that drinking light to moderate amounts of alcohol may decrease the risk of ischemic stroke. Conversely, heavy drinking is linked to an increased risk of intracranial hemorrhage and ischemic brain injury. Chronic alcohol consumption is believed to increase the risk of hemorrhage through alcohol-induced hypertension, impaired hemostasis, decreased circulating levels of clotting factors, excessive fibrinolysis, and disseminated intravascular coagulation. In addition, cardiac dysrhythmias or cardiomyopathy may precipitate thromboembolic phenomena.81 Fifty percent of middle-aged patients (45–55 years) with no apparent cause for their cerebrovascular accidents suffer from alcoholism.10

Myopathy

Several studies have reported elevated creatine kinase in patients who had been on drinking sprees. Although these patients are asymptomatic, many have muscular tenderness on examination. Cardiomyopathy often coexists in these patients. Both acute and chronic forms of this myopathy are recognized. Many chronic alcoholics have mild proximal muscle weakness and muscle atrophy on examination.

Type II muscle fiber atrophy is found in chronic alcoholic myopathy. The role of ethanol, toxic metabolites, hypokalemia, hypocapnea, hypomagnesemia, hyponatremia, malnutrition, unrecognized compression or crush injury, and other factors in the pathogenesis of atrophy remains to be determined.82

Movement Disorders

Alcohol withdrawal is associated with tremor, ataxia, and myoclonus. Acute alcohol consumption ameliorates essential tremor and myoclonus. Persistent tremor is occasionally seen in chronic alcoholism. This alcoholic tremor may persist up to 1 year after abstinence. Although the pathophysiology is poorly understood, studies have confirmed that essential tremor and alcoholic tremor are distinct entities.81

Alcoholic Cerebellar Degeneration

Characterized by ataxia of the extremities, cerebellar ataxia of alcoholism results in a wide-based stance and uncoordinated gait. Lower extremity involvement predominates, although the arms may rarely be involved. Pathologic changes consist of degeneration of elements in the cerebellum, especially the Purkinje cells. The diagnosis is based on history, physical examination, and magnetic resonance imaging or CT (which show severe cerebellar atrophy). Treatment consists of abstinence, adequate nutrition, and thiamine.82

Infections

Alcohol is an immunosuppressive drug. Animal and human studies have implicated acute and chronic ethanol ingestion in causing decreased serum bactericidal activity, impaired mononuclear phagocyte function, diminished cell-mediated immune functions, reduced delayed hypersensitivity reaction, and defective polymorphonuclear neutrophils. Neutropenia may be found in up to 8% of hospitalized alcoholics.83

Alcohol ingestion prevents the normal delivery (chemotaxis) of polymorphonuclear neutrophils to sites of bacterial infection. Chronic alcohol exposure depresses the development and expression of cell-mediated immunity. This depression may contribute to the high incidence of tuberculosis and head, neck, and upper gastrointestinal cancers in alcoholics. Alcohol’s suppression of macrophage function reduces the reticuloendothelial system’s ability to clear particles. This may contribute to spontaneous bacteremia, spontaneous peritonitis, and pneumonia. Primary antibody response to new antigens is also depressed. Malnutrition and liver failure also contribute to an immunocompromised state in the alcoholic.

The most common infection seen in alcoholism is pneumonia. Associated risk factors for pneumonia in alcoholics include smoking, decreased ciliary function, decreased surfactant production, depressed cough reflex, malnutrition, and poor oral hygiene. Although alcoholic patients may contract a variety of bacterial pneumonias, Streptococcus pneumoniae is still the most common organism. Periods of alcoholic stupor with incomplete glottic closure and subsequent aspiration can lead to aspiration pneumonia or lung abscess. Klebsiella pneumoniae, classically associated with alcoholism, is currently more common in patients with cytotoxic chemotherapy, hematologic malignancy, and transplantation than in the chronic alcoholic. In addition, these infections now tend to be nosocomial rather than community acquired.83

Alcoholism is also associated with a 55 times higher incidence of tuberculosis than that of the general population. Alcoholism does not seem to influence the long-term relapse rates in tuberculous patients if they have closely supervised therapy of adequate duration. Homeless alcoholic patients are an important reservoir of tuberculosis in the United States. Spontaneous bacterial peritonitis occurs in cirrhotic patients with ascites and has a high mortality rate (50–90%). A common presentation consists of fever, abdominal pain, and leukocytosis. Escherichia coli, K. pneumoniae, and S. pneumoniae are the most common bacteria cultured from the ascitic fluid. Patients with ascites and fever should have a diagnostic paracentesis as part of their evaluation.

Hepatitis C appears to be related to concomitant IV drug use rather than the direct effect of alcohol abuse. Alcoholism is associated with a high prevalence of unsafe sexual behavior
and human immunodeficiency virus (HIV) seropositivity, with greater immunologic changes in HIV-1-positive patients who also consume alcohol.

The most serious impairment of host defenses occurs with alcoholic cirrhosis and liver failure. Chronic alcoholics with cirrhosis develop spontaneous bacteremia and have a higher incidence of bacterial endocarditis. Alcoholism and cirrhosis increase the mortality rate in pneumococcal meningitis.

Fever in the chronic alcoholic may have a wide variety of causes. The most common infection remains pneumonia. Occult urinary tract infections are more common than expected. The most common noninfectious causes of fever are alcohol withdrawal and alcoholic hepatitis. A leukocytosis is associated with both, often making the differentiation from infection difficult. Both infectious and noninfectious causes may coexist, as well as multiple sources of infection. Most febrile alcoholics without an identifiable source are best served by hospitalization.

**Endocrine Effects**

Alcohol dependence adversely affects many endocrine systems. Both peripheral thyroid hormone dysfunction and central hypothalamic-pituitary-thyroid axis deregulation are seen. Male hypogonadism and feminism are seen in chronic male alcoholics. Alcohol’s effects on both the testes and the hypothalamus decrease testosterone production in men. Alcoholics. Alcohol’s effects on both the testes and the hypothalamus decrease testosterone production in men. Alcoholics.

It is difficult to distinguish between obesity, alcoholism, and Cushing’s syndrome because facial fullness, weakness, fatigue, and easy bruising related to thinning of the skin can be present in all three conditions. An alcohol-induced pseudo–Cushing’s syndrome has also been described that resolves with abstention.

**Metabolic Effects**

**Carbohydrates**

Alcohol-induced hypoglycemia occurs in 1 to 4% of intoxicated ED patients. It is more frequently seen in chronic alcoholics. Coma, seizures, hemiparesis, and a variety of other neurologic signs have been described in patients presenting with alcohol-induced hypoglycemia. Starvation, depletion of liver glycogen stores, decreased plasma cortisol levels, impaired release of growth hormone, and inhibition of gluconeogenesis contribute to this phenomenon.

Hyperglycemia and diabetes may be found in chronic alcoholism. However, studies in men that explored the association between light to moderate alcohol use and risk for type 2 diabetes suggest that an inverse relationship may exist. Alcohol abuse can lead to chronic pancreatitis, resulting in underproduction of insulin by the damaged pancreatic cells. Alcohol also impairs peripheral glucose utilization, causing a relative insulin resistance (similar to type 2 diabetes). In diabetic patients, alcohol can induce hypoglycemia and also mask the signs of hypoglycemia. This effect has been found to be more prominent in the fasting state.

Ethanol can be found as an active ingredient in hundreds of prescription and nonprescription drugs. Concentrations of 60% or greater can be found in some oral preparations, which pose a potential threat to the pediatric patient by producing profound intoxication or alcohol-induced hypoglycemia. Children are particularly susceptible because of smaller glycogen stores and delayed diagnosis. Hypoglycemia can also be seen with aspirin intoxication, prior gastric bypass surgery, hypothermia, or overwhelming sepsis.

**Lipids**

A reversible hypertriglyceridemia occurs in many chronic alcoholics. Ethanol increases hepatic synthesis of triglycerides. Abstention is necessary to reduce elevated triglyceride levels. Except for its relationship to fatty infiltration of the liver, the clinical significance of this hyperlipidemia is unknown.

**Uric Acid**

Hyperuricemia is common with heavy drinkers. Alcohol increases urate levels by inhibiting renal clearance of urate, and it increases urate synthesis by enhancing the turnover of adenine nucleotides. Although alcohol use can exacerbate primary gout, it is unlikely that alcohol alone can induce secondary gout.

**Electrolytes**

Ethanol has numerous effects on electrolytes and mineral metabolism, as summarized in Table 183-2. Hyponatremia and hypokalemia are common findings in active drinkers. Vomiting, diarrhea, magnesium depletion, malnutrition, and metabolic alkalosis contribute to these abnormalities.

Alcoholism is the most common cause of severe magnesium deficiency in adult outpatients. Thirty percent of alcoholics are magnesium deficient as a result of malabsorption, malnutrition, diarrhea, vomiting, and increased urinary losses. Correcting the magnesium level has been shown to improve liver enzyme levels and to correct other electrolytes.

Hypocalcemia is common in alcoholic patients with magnesium depletion. The mechanism is related to diminished parathyroid hormone secretion, decreased tissue responsiveness to parathyroid hormone, decreased vitamin D metabolism, and decreased calcium release from bone independent of parathyroid hormone. Correction of magnesium depletion is necessary to restore calcium to normal levels. Hypoalbuminemia, pancreatitis, or vitamin D deficiency may also contribute to low serum calcium or low total body stores of calcium in alcoholic patients.

Hyppophosphatemia is found in 30 to 50% of admitted patients with alcoholism. Phosphorus depletion results from malnutrition, vomiting, respiratory alkalosis, diarrhea, enhanced release of calcitonin, phosphate-binding antacids, and urinary loss (related to vitamin D deficiency and secondary hyperparathyroidism). Hypophosphatemic patients are often found to have low magnesium levels. Rehydration, carbohydrate repletion, and parenteral alimentation further exacerbate phosphorus depletion. Glucose bolus and infusion have been shown to produce a significant decrease in serum inorganic phosphate levels. Severe hypophosphatemia (<1 mg/dL) has been associated with acute respiratory failure; myocardial depression; dysfunction of erythrocytes, leukocytes, and platelets; CNS irritability; and rhabdomyolysis.

Although chronic alcoholics requiring admission often have potassium, magnesium, and phosphate depletion, empirical treatment with potassium and phosphate is discouraged.
Serum levels and renal function should be determined. Unintended hyperkalemia and hyperphosphatemia can produce significant morbidity, and phosphate infusion exacerbates hypocalcemia if present. Because most magnesium is intracellular, a normal serum magnesium level does not necessarily mean that total body magnesium levels are normal. If the serum level is normal, total body levels may be either normal or low. As long as renal function is adequate, empirical magnesium treatment can be considered. Abstinence and a proper diet resolve electrolyte and nutritional deficiencies in the ambulatory alcoholic patient who is healthy enough to be treated as an outpatient.

Correcting these problems is usually the responsibility of the admitting physician. Therapy may be initiated in the ED. In most cases, oral supplementation is sufficient. To correct more severe cases of hypokalemia and hypophosphatemia, 20 mEq of potassium phosphate per liter of IV solution can be given. Two grams (16.2 mEq) of magnesium sulfate (maximum 30 to 40 g/day) may be given IV at a rate not to exceed 150 mg/minute (equivalent to 1.5 mL of 10% solution).

Alcoholic Ketoacidosis

Alcoholic ketoacidosis most frequently occurs in severe chronic alcoholics who have had a recent binge followed 1 to 3 days later by protracted vomiting, decreased food intake, dehydration, and abstinence. Nausea, vomiting, and abdominal pain are common presenting complaints. These patients have tachypnea, dehydration, ketonuria, and little or no glucosuria. Serum glucose levels are usually less than 200 mg/dL. Normal blood pH may be found despite ketonemia because of coexisting respiratory alkalosis and metabolic alkalosis.

The exact mechanism responsible for the increase in ketone bodies is unclear. Acute starvation superimposed on chronic malnutrition, as well as release of an alcohol-induced block in ketogenesis allowing marked ketosis, may explain the disorder. An increased ratio of reduced (NADH) to unreduced nicotinamide adenine dinucleotide (NAD) in the alcoholic predisposes to the accumulation of β-hydroxybutyrate and the inhibition of gluconeogenesis, which may underlie the common occurrence of hypoglycemia in alcoholic ketoacidosis.

Alcoholic patients with metabolic acidosis present an interesting dilemma. Most of these patients have an increased anion gap acidosis. In addition, a very high osmolal gap (>25 mOsm/kg) is very specific (88%) for methanol or ethylene glycol ingestion. Quick examination of a urine specimen in the ED can be helpful in determining the cause of the acidosis: Glucosuria may suggest diabetes; crystalluria can be seen in ethylene glycol poisoning; low specific gravity, proteinuria, and casts can be seen in renal failure; leukocytes and bacteria are present with urosepsis; and significant ketones in an otherwise normal urine may indicate starvation or alcoholic ketoacidosis.

Treatment of alcoholic ketosis consists of normal saline, glucose, thiamine, and correction of hypokalemia. This can be accomplished with 5% dextrose in normal saline and either 30 mEq of potassium chloride or 30 mEq of oral potassium. Bicarbonate is seldom necessary for the uncomplicated case but may be considered in the rare patient who has a pH less than 7.1. If no serious complicating illness is present, the ketosis is reversed in 12 to 24 hours with this treatment.

Clinical improvement may be detected within hours of therapy. Nevertheless, most patients with alcoholic ketoacidosis need 1 or 2 days of inpatient treatment to correct fluid, electrolyte, and nutritional balance.

Hematologic Effects

The alcoholic presents the clinician with a myriad of hematologic abnormalities. The direct toxic effect of ethanol and its metabolites, secondary nutritional deficiency, and hepatic disease, individually or in combination, affect red blood cells (RBCs), white blood cells (WBCs), platelets, hemostasis, and the immune system.
Anemia

Several mechanisms are responsible for anemia, which is common in the alcoholic. Megaloblastic anemia resulting from folate deficiency is the most common anemia in alcoholics. The mean corpuscular volume (MCV) is typically increased but may be normal when iron deficiency coexists. Malnutrition, inability of the cirrhotic liver to store folate, excessive urinary loss, and malabsorption decrease folate stores. Alcohol accelerates the development of megaloblastic anemia in individuals with depleted folate stores (MCV > 100 fl) by an unknown mechanism.

Macrocystosis is the most common hematologic manifestation of the chronic alcoholic. It may be caused by folate deficiency, reticulocytosis (the younger reticulocytes are larger), liver disease (producing an abnormal lipid coating of RBC membrane), or vitamin B₁₂ deficiency. The most common condition is idiopathic macrocytosis of alcoholism.

Iron deficiency anemia is common among alcoholic patients and usually is a result of blood loss from the gastrointestinal tract. Alcohols are subject to chronic inflammatory diseases such as endocarditis, tuberculosis, empyema, lung abscess, malignancy, and hepatic disease. These chronic inflammatory illnesses can produce the anemia of chronic disease, a mild microcytic or normocytic anemia in which the serum iron is low, the total serum iron–binding capacity is low or low-normal, and serum ferritin is increased. With iron deficiency anemia, the serum iron is decreased, the total serum iron–binding capacity is elevated, and serum ferritin is decreased.

Ethanol also has a direct toxic effect on erythropoiesis. Bone marrow biopsies reveal vacuolization of erythroid precursors, resulting in decreased reticulocytosis and a reversible sideroblastic anemia. Sideroblastic anemia, usually in the presence of malnutrition with pyridoxine deficiency and folate deficiency, occurs in 25 to 30% of anemic alcoholics.

Hemolytic Syndromes and Erythrocyte Abnormalities

A variety of hemolytic syndromes have been associated with alcoholism. Zieve syndrome is a transient hemolytic anemia with hyperlipidemia and fatty infiltration of the liver. Acquired stomatocytosis, a condition characterized by abnormally shaped RBCs that are susceptible to hemolysis and acanthocytosis (spur cell anemia), has been associated with alcohol abuse. Zieve syndrome and stomatocytosis may be reversed with abstinence. Spur cells are RBCs with spicules. Spur cell hemolytic anemia is frequently linked to alcoholics with cirrhosis. With jaundice and splenomegaly, spur cell hemolytic anemia is usually fatal. When severe hemolysis is present, remission is rare.98

These syndromes are associated with liver disease, which alters the lipid composition of the RBC membrane, and congestive splenomegaly, which produces hemolysis. Severe hypophosphatemia (<1 mg/dL) can also result in hemolysis. The pathogenesis of these syndromes, specificity for alcoholism, and relationship to membrane injury or hemolytic anemia are uncertain.97

Leukocyte Abnormalities

Leukopenia is often seen in the alcoholic patient and has several possible causes. Sepsis, folate deficiency, and hypersplenism all lead to a decreased WBC count. Alcohol has a direct toxic effect on WBC production in the bone marrow. Granulocyte mobilization (chemotaxis) and adherence are also impaired, resulting in a decreased inflammatory response.

Platelet Disorders

Thrombocytopenia can occur with folate deficiency, sepsis, disseminated intravascular coagulation, or splenic sequestration. The direct toxic effects of alcohol decrease measured survival time and impair production of platelets in the bone marrow, but marrow toxicity will rarely reduce the platelet count below 30,000. Qualitative platelet function is also impaired. Binge drinking is associated with a reactive thrombocytosis potentially responsible for acute stroke and sudden death.99

Hemostasis

Alcoholic patients develop a bleeding diathesis for many reasons, including thrombocytopenia, qualitative platelet disorders, deficient production of hepatic clotting factors, gastrointestinal variceal formation, and vitamin K deficiency. A complete blood count, peripheral smear, platelet count, reticulocyte count, thrombin time, prothrombin time/INR, and partial thromboplastin time are required to evaluate episodes of significant bleeding. Bleeding associated with coagulation abnormalities may require immediate intervention. Fresh frozen plasma can be given for immediate correction of coagulation factor depletion; vitamin K (10 mg IV) takes 6 to 10 hours to reverse the vitamin K–dependent factors II, VII, IX, and X. Because of poor diet and impaired hepatobiliary function, alcoholics may have insufficient vitamin K storage and benefit from vitamin K delivery. However, alcoholic patients with profound liver failure are unable to produce precoagulation factors II, IV, VII, IX, and X, and vitamin K therapy is futile. Platelet transfusions should be started in the ED for adult patients with active bleeding whose platelet count is less than 50,000/mL.

Oncologic Effects

Worldwide, an annual total of 389,000 cases of cancer representing 3.6% of all cancers are alcohol related.102 Chronic alcohol use is associated with an increased incidence of upper alimentary and respiratory tract cancers. The direct or indirect mechanism (e.g., tumor promoter) producing this relationship remains to be explained. Increasingly, acetaldehyde appears to play an important role in the carcinogenic effects on the upper digestive tract.103 Ethanol may promote carcinogen activation by its effect on the cytochrome P450 system through (1) nutritional deficiencies (particularly vitamin A) that accompany prolonged heavy drinking, (2) contaminants such as nitrosamines and hydrocarbons, or (3) increased permeability of mucous membranes to other carcinogens.103 Smoking certainly has an additional role as a cause of neoplasia and is difficult to isolate in these studies.

In general, alcohol increases the risk of cancer of the mouth, pharynx, larynx, and esophagus. Chronic hepatitis B infection may sensitize the liver to alcohol, producing hepatocellular carcinoma. Women who consume two to five drinks per day have a relative risk of 1.41 for invasive breast cancer compared with nondrinkers.102 Moderate alcohol consumption leads to an increased risk of colorectal and prostate cancer.103 The association is less clear between alcohol consumption and lung or pancreatic cancer.104

Hypothermia

Acute alcohol ingestion is one of the most common precipitating factors for accidental hypothermia and exacerbates hypothermia of other causes. Several studies have implicated acute
ethanol ingestion in 33 to 73% of patients presenting with a core temperature less than 35°C. Alcohol is associated with the following: depressed hypothalamic thermoregulation, peripheral vasodilation producing heat loss, CNS depression, sepsis, inability to shiver, hypoglycemia, and an increased risk of environmental exposure. Hypothermia may be the presentation of Wernicke’s syndrome, possibly caused by lesions of the posterior hypothalamus, hypoglycemia, or sepsis. Intoxicated patients also may have slower rewarming rates.

### Psychiatric Effects

Forty-five percent of alcohol-dependent adults are diagnosed with one or more additional psychiatric conditions during their lifetime. Of alcoholic men admitted to a psychiatric ward, approximately 40% have a psychiatric disorder unrelated to substance abuse. In particular, antisocial personality disorder, schizophrenia, mood disorders, and anxiety disorders are found in this group. Up to 17% of all alcoholics eventually die by suicide.106,107

Depression and antisocial personality are the two most common psychiatric disorders that correlate with alcoholism, with a prevalence in most studies of 30 to 60%, respectively. Chronic alcohol use can produce an imbalance in the serotonergic system. This imbalance may lead to increased anxiety, aggression, and depression. Interestingly, aggressive behavior is linked more strongly to depression than to alcohol dependence.108 Secondary depression may be caused by alcoholism, or the primary affective disorder may be present with secondary alcoholism. Mild depressive symptoms are also common in alcohol withdrawal. Antisocial individuals are at high risk for alcoholism and drug dependence, although an unstable, unhappy childhood environment appears to be more important to the development of sociopathy than alcohol. Alcoholism, major depression, and antisocial personality all predispose to suicide attempts, and interaction among the three is particularly dangerous.

As many as 50% of alcoholic women exhibit symptoms of other psychiatric disorders. Although many patients turn to alcohol because of a primary psychiatric illness, alcohol can produce anxiety, hallucinations, paranoia, and depression and has been associated with a nearly twofold increased risk of suicide.106

An alcoholic patient who presents with an apparent psychiatric disorder poses a diagnostic dilemma. Does the patient have a primary affective disorder with secondary alcoholism, or is the patient manifesting anxiety or depressive behavior because of alcoholism? In general, alcoholic patients with psychiatric disorders are best treated with medications that are specific for their psychiatric condition.5

Many alcoholics with mild depression have spontaneous resolution of symptoms with abstinence. Nevertheless, depression meeting DSM-IV criteria is best treated with antidepressants.109,110 If abstinence can be achieved, underlying psychiatric disorders are more easily diagnosed and treated.

### ALCOHOL-DRUG INTERACTIONS

Alcohol is associated with a vast number of drug interactions (Table 183-3). These may occur through several mechanisms: (1) altered absorption; (2) enhanced metabolism and activated toxic metabolites through the hepatic CYP2E1 pathway; (3) additive or synergistic effects; (4) disulfiram-ethanol–like reactions; and (5) congeners, which are compounds found in alcoholic beverages. In general, chronic alcoholism is associated with an increased rate of drug clearance resulting from enhanced metabolism and enzyme induction (cytochrome P450 system). Conversely, acute alcohol intoxication reduces clearance for other drugs, increasing their serum concentration because of competition for a partially shared detoxification pathway.111

#### Altered Absorption

Propranolol may delay gastric emptying and thus prolong gastric contact. Other compounds, such as erythromycin and metoclopramide, may increase gastric emptying.

#### Enhanced Metabolism and Toxic Metabolites

Most alcohol is metabolized by ADH. A small percentage of alcohol is metabolized by the MEOS–cytochrome P450 system, which is also responsible for the metabolism of various drugs. The MEOS metabolic pathway is enhanced in chronic alcoholics. Therefore, the induction of MEOS is associated with the acceleration of the degradation of these other drugs. For example, the half-lives of warfarin, phenytoin, and isoniazid are 50% shorter in abstaining alcoholics than in nondrinkers. Barbiturates, diazepam, propranolol, and rifampin may have increased rates of clearance when taken by chronic alcoholics. This effect can persist for days to weeks after the cessation of drinking.68,112

Acetaminophen is the most widely used analgesic in the United States and is often recommended to alcoholic patients instead of NSAIDs to prevent gastritis. Chronic alcohol ingestion may enhance acetaminophen hepatotoxicity by accelerating the biotransformation to a toxic metabolite. There are a few case reports of severe or lethal acetaminophen toxicity in alcoholics taking therapeutic doses of the analgesic. Greatly elevated AST levels (3000 to 48,000 in one series), increased ALT levels, and greatly elevated prothrombin/INR times help to distinguish acetaminophen hepatotoxicity from alcoholic hepatitis.111 Increased vulnerability seems to occur immediately after cessation of drinking. A synergistic effect apparently occurs with alcohol, fasting, and acetaminophen use in combination with depleted glutathione stores. Other studies have failed to demonstrate increased hepatotoxicity after acetaminophen overdose in heavy drinkers versus nondrinkers.113

#### Additive or Synergistic Effects

Alcohol has long been known to have additive or even synergistic effects with several drugs. Acute intoxication decreases the rate of drug metabolism, which is at least partially explained by competition for the same enzymatic process in the liver. For example, ethanol has additive sedative effects when taken with first-generation antihistamines, barbiturates, cyclic antidepressants, benzodiazepines, phenothiazines, propoxyphene, propofol, and narcotics. Alcohol may also increase the activity of methylxanthines and nitroglycerin. Alcohol can increase tetracycline levels by 30%. Selective serotonin reuptake inhibitors do not appear to affect alcohol kinetics or psychomotor performance.

When cocaine and ethanol are taken concomitantly, a third drug is formed. Cocaethylene is a neurologically active compound, significantly more toxic than cocaine to the heart, liver, and brain, which is more addicting and more lethal than cocaine alone. Cocaethylene produces a higher incidence of confusion, lower mean Glasgow Coma Scale (GCS) scores, and a higher incidence of violent trauma and more often requires endotracheal intubation.114 Hemodynamically, these patients demonstrate an elevated heart rate (1.5–5 times normal) and blood pressure greater than that with either drug alone. Sudden death is increased 18- to 25-fold over that associated with use...

of cocaine alone. Plasma levels of cocaine in this combined group were higher than in those who used cocaine alone.115

**Gastrointestinal Bleeding**

Ethanol increases aspirin-induced prolongation of bleeding time and reduces the metabolism of warfarin, leading to increased anticoagulant effects. There is an increased risk of upper gastrointestinal bleeding when alcohol is combined with NSAIDs. This may be the most dangerous additive or synergistic effect of alcohol.116

**Disulfiram and Similar Reactions**

Most patients pretreated with disulfiram (Antabuse) who then consume even small amounts of alcohol experience an extremely unpleasant reaction. These patients develop a hypersensitivity to ethanol and experience a direct response within 15 minutes and lasting 30 minutes to several hours. The reaction consists of skin flushing on the head that spreads to the trunk, along with nausea, vomiting, headache, chest and abdominal discomfort, diaphoresis, vertigo, palpitations, and confusion. A severe reaction may produce hypotension, seizures, and dysrhythmias. Disulfiram-ethanol reaction is thought to occur by either the accumulation of acetaldehyde secondary to inhibition of the aldehyde dehydrogenase enzyme, which may be deficient in some Asians, or another unknown toxic factor. This incapacitating reaction has been used to discourage chronic alcohol ingestion.

A similar but milder disulfiram-ethanol–like reaction has been described when alcohol combines with several different drugs. The reaction may occur days to weeks after the last dose of medication. Four cephalosporins (cefamandole, cefoperazone, cefotetan, and moxalactam), metronidazole, chloramphenicol, griseofulvin, nitrofurantoin sulphonamides, all sulfonylureas, and chloral hydrate have been reported to produce this reaction when combined with alcohol ingestion. Life-threatening toxic reactions between griseofulvin and small amounts of ingested alcohol have been reported.117

Treatment for disulfiram reaction is symptomatic and includes IV fluids, dopamine for persistent severe hypotension, observation, an antiemetic, and cardiac monitoring.

**Congeners**

Congeners are compounds in alcoholic beverages other than ethanol and water. Some beers and wines contain tyramine, Hypertensive crisis may occur in patients treated with monoamine oxidase inhibitors who drink these alcoholic beverages.
Oral Hypoglycemics

Oral hypoglycemic agents and alcohol can interact and produce unpredictable glucose levels. Profound hypoglycemia can occur when alcohol and oral hypoglycemic agents are combined. Patients taking metformin may have an increased risk for developing lactic acidosis when combined with heavy drinking. A disulfiram-ethanol–like reaction has been described with many hypoglycemic agents.112

THE ADOLESCENT PATIENT

Injury is the most common cause of adolescent morbidity and mortality. Alcohol is often associated with these injuries.118 Adolescent drinking is associated with a myriad of negative consequences, including suicide, driving under the influence and resultant fatalities, unsafe or increased sexual activity, sexual assault, and date rape. Seventy-eight percent of high school students have tried alcohol, and 30% admit to binge drinking at least once a month.119

The age of drinking onset may be an indicator for increased risk of alcohol-related injury. Adolescents who began drinking regularly before age 14 years were at least three times more likely to be diagnosed with alcohol dependence than those who began drinking at age 21. In addition, adolescents who began drinking before age 21 were significantly more likely, during their lives, to have been injured while under the influence of alcohol.120

Adolescent drinkers account for nearly 20% of all alcohol consumption, spending an estimated $22.5 billion.121

THE ELDERLY PATIENT

Active problem drinking is found in 14% of elderly (older than 65 years) ED patients. Fifty percent of older people drink alcohol, and 2 to 4% meet criteria for alcohol abuse or dependence. Common screening tests (e.g., CAGE) tend to be less sensitive in this age group. Alcohol may exacerbate underlying disease by masking anginal chest pain, worsening hypertension, and inducing dysrhythmias.122 However, elderly people consuming low to moderate levels of alcohol may have a decreased risk for developing dementia and heart failure.123

More than 90% of people age 65 or older use more than one prescribed medication.124 Aging alters gastrointestinal absorption, lowers volume of distribution, diminishes homeostatic responses, and reduces renal and hepatic function.112 Elderly people also demonstrate increased end-organ sensitivity, particularly involving the CNS, with concomitant drug use. Therefore, elderly patients are at increased risk for alcohol and drug interactions.

Elderly patients are also more likely to have neuropsychiatric complications of alcoholism. Sleep problems, anxiety, depression, and dementia are often observed. Alcohol has been involved in one third of suicides in elderly people. Older subjects have also been shown to perform less well on tests of perception and attention than younger subjects at all blood alcohol levels. This may result in an increased risk of fractures from falling and osteoporosis.

Overall, prognosis is age related with respect to cirrhosis. One study reported a 1-year mortality rate of 50% in those older than 60 versus 7% for those younger than 60.125

PREGNANCY

More than 2000 scientific reports have confirmed alcohol’s teratogenic effects. According to the National Institute on Drug Abuse, almost 19% of all children born in the United States have been exposed to alcohol during gestation.125 Pregnant women who reported any use of alcohol, binge drinking, or frequent drinking were more likely to be older than 30 years, employed, and unmarried.126

Fetal alcohol syndrome is characterized by a triad of CNS defects, including mild to moderate mental retardation; dysmorphology, involving mostly facial structures; and growth deficiencies, usually consisting of short stature and microcephaly.127 Fetal alcohol syndrome is now considered the most common identifiable source of mental retardation. Children exposed to prenatal alcohol exhibit increased activity levels, cognitive and attention deficits, perseverative behavior, and language and motor problems, which persist into adulthood.128

Ethanol rapidly diffuses across the placenta and is distributed to all fetal tissue with a predilection for gray matter. Although infants of mothers who drink heavily have the poorest outcome, children of mothers who consume only two or three alcoholic drinks a day also display abnormalities. Even in the absence of growth retardation or congenital abnormalities, children born to women who consume excessive alcohol during pregnancy appear to be at increased risk for attention deficit disorders. These findings are referred to as fetal alcohol effects.

No known safe amount of alcohol consumption during pregnancy exists. The American Academy of Pediatrics recommends abstinence from alcohol for women who are pregnant or who are planning a pregnancy.129

TRAUMA

Alcohol and trauma are inextricably linked. Independently, the tragic effects of each are numerous; in combination, they are staggering. Injury is the leading cause of death between the ages of 1 and 44 years. It accounts for more than 500,000 injuries per year. In the United States, alcohol is the major risk factor for virtually all categories of intentional and unintentional injury. Besides increasing the frequency and severity of injury, alcohol significantly complicates the management of the trauma victim.5 Alcohol intoxication often complicates the initial assessment of injury severity, resulting in an increased need for invasive diagnostic and therapeutic procedures (e.g., intubation, CT scan, and intracranial pressure monitoring).130

Alcohol may diminish the patient’s capacity to respond to hemorrhagic shock by altering hemodynamic effects and acid-base balance. Volume depletion as a result of the diuretic effect of alcohol or vomiting can impair the reserve of the intoxicated trauma patient. Peripheral vasodilation caused by alcohol may contribute to hypotension and hypothermia. Although these effects may be minimal, they underscore the need for early and adequate fluid resuscitation in these patients. Intoxicated patients with severe non-neurologic trauma may have lower blood pressures and carbon dioxide levels (indicative of a compensatory hyperventilation) on hospital arrival than sober patients. More important, a poorly understood cardiac depressant effect also increases the depth of shock and volume requirements for resuscitation. Alcohol-induced skin vasodilation may be accompanied by an increase in skeletal muscle, mesenteric and renal bed constriction, and left ventricular stroke. Thus, the overall effect on systemic vascular resistance and blood pressure may be balanced.131

Intoxication renders the signs and symptoms of intra-abdominal and retroperitoneal injury less reliable than usual. If the risk of an intra-abdominal injury exists, further evaluation (e.g., ultrasonography and CT) should be considered.

Alcohol intoxication predisposes to abdominal wall laxity and thus less protection from blunt trauma.132 These patients
are also likely to have full stomachs, increasing the risk of gastric injury after trauma and predisposing to vomiting and aspiration, especially during airway management. The fatty liver changes of alcoholism can result in hepatomegaly. Portal hypertension in alcoholics may produce splenomegaly. These organs can become more vulnerable to the effects of trauma because of their enlarged size, protrusion beneath the protection of the ribs, and increased intracapsular pressure.

Alcohol intoxication contributes to CNS injury in many ways. It is associated with aggressive behavior, impaired reflexes and coordination, and inappropriate avoidance responses. A higher degree of trauma to the spinal cord and much worse neurologic and functional recovery occur in patients who are intoxicated during trauma compared with sober patients. Experimental evidence suggests that alcohol acts synergistically with mechanical injury of the spinal cord to amplify the trauma response by increasing edema formation within the contused tissue.

No consensus exists on the indications for an emergency CT scan in patients with “minor head injury” (loss of consciousness, post-traumatic amnesia, GCS score of 14–15, and normal neurologic examination). One disturbing prospective study found that GCS plus 1 hour of observation was unable to predict positive head CT scans in intoxicated patients with minor head trauma. Patients with signs of head trauma and focal or generalized seizures need an urgent CT scan. CT scans of the head should be performed for any patient with deteriorating mental status, focal neurologic findings, new-onset seizures even without obvious signs of history of trauma, failure to improve over time, or mental status changes out of proportion to the degree of intoxication.

The good news is that during the past 20 years, there has been a decline in the number of alcohol-related fatalities. Five states (Hawaii, Illinois, Indiana, Pennsylvania, and Utah) have enacted mandatory hospital and/or provider reporting laws.

**ADMISSION GUIDELINES AND DISPOSITION**

Optimal outpatient therapy for chronic alcoholics includes involvement of concerned family or friends to ensure that the patients take their medications properly, appear at their follow-up appointments, abstain from alcohol, and maintain an adequate diet. Alcoholic patients who undergo outpatient treatment need close supervision; therefore, a follow-up clinic appointment within 24 to 48 hours should be considered.

Most alcoholics suffer from a combination of medical, psychiatric, and social problems. Hospitalization is often necessary to diagnose and treat these multiple problems. Moreover, with alcoholics who are no longer able to care for themselves, hospitalization is often dictated for this reason alone. Unfortunately, many managed care and Medicaid plans limit or do not cover inpatient detoxification. In choosing medical versus psychiatric admission, a medical illness usually takes priority.

**Acute Intoxication**

Acute intoxication alone seldom requires admission. However, combined alcohol-drug overdose or associated medical, psychiatric, or social problems may require hospitalization. Acute alcohol intoxication is a diagnosis of exclusion reached after adequate observation to ensure that the altered mental status resolves.

Alcohol levels that may be tolerated by an adult can be lethal in children. It is prudent to admit children with acute intoxication unless close psychosocial follow-up can be ensured. Children presenting with hypoglycemia or medical complications should be admitted. Child abuse or neglect should be considered.

**Alcohol Withdrawal**

Patients with signs of major withdrawal (fever, hallucinations, confusion, and extreme agitation) require admission. Patients with mild alcohol withdrawal can be observed in the ED. After 4 to 6 hours of observation and treatment, the alert, oriented patient whose vital signs, physical examination, and appropriate laboratory analysis are within normal limits may be released. Optimally, the patient can be sent to an alcohol treatment center or sent home with an accompanying competent adult for continued observation over several days.

**Seizures**

Patients experiencing their first ARS may be admitted. Admission allows initiation of drug therapy, diagnostic evaluation, and continued monitoring of the patient’s status. However, the alcoholic patient with a first-time ARS may be discharged to a suitable social situation when (1) the patient’s alcohol withdrawal is mild and easily controlled either by supportive care or with low-dose benzodiazepines; (2) the diagnostic workup, including a head CT scan, is unremarkable; (3) the patient has had less than two seizures; and (4) the patient has been observed to be alert and oriented, with normal vital signs, physical examination, and laboratory studies, during the 6 hours since the last seizure, and appropriate outpatient follow-up can be ensured.

Patients with a documented history of ARS can be discharged if they have had no more than two ARSs during a 6-hour period with a lucid interval between seizures and are observed to be seizure free and at baseline mental and physical status for at least 6 hours after their last ARS. Three to five brief, self-limited seizures may occur with alcohol withdrawal seizures. Nevertheless, admission for patients with two or more seizures is advised because of the potential for deterioration to status epilepticus. This is especially appropriate in the malnourished, immunocompromised, homeless, or noncompliant alcoholic patient.

Patients with partial seizures or focal neurologic findings on physical examination require admission unless these findings have been previously documented. Patients with seizures associated with head trauma or with mixed alcohol-drug withdrawal are admitted. Status epilepticus or recurrent seizures during observation in the ED indicate a lack of seizure control also requiring hospitalization.

**Psychiatric and Social Problems**

Alcoholic patients requiring admission with acute intoxication, ARS, alcohol withdrawal, or medical or surgical disorders are usually best managed on acute care floors rather than by a general psychiatric service. Some psychiatric and social conditions in the alcoholic can be better handled on a general psychiatric unit, including psychosis, exacerbation of schizophrenia, depression with suicidal tendencies, any patient who is a danger to self or others, or alcoholic hallucinosis with an otherwise clear sensorium.

Patients who are no longer able to care for themselves may also require admission. Although these patients’ ultimate destination is a rehabilitation center or a board-and-care program, hospitalization may be necessary to rule out medical or psychiatric illness and to treat impending withdrawal symptoms. Patients who wish to stop drinking are usually admitted to a
detoxification unit to treat impending withdrawal. Data and interest are increasing for outpatient drug therapy in alcohol dependence. The Food and Drug Administration has approved disulfiram, naltrexone, acamprosate, and topiramate for treatment of alcohol dependence.\(^2\) Naltrexone, ondansetron, acamprosate, or acamprosate plus naltrexone have had mixed results facilitating abstinence.\(^{136,137}\) The role of medications in combination with behavioral therapy is actively investigated.\(^{138,139}\) Brief intervention—10 to 15 minutes of counseling—can decrease drinking compared with no intervention.\(^{140}\) Referral and brief intervention are warranted.\(^{141}\) Most communities have either an Alcoholics Anonymous chapter or a treatment center for anyone who desires help with alcohol. In smaller communities, clergy or social workers can usually arrange rehabilitation.

Alcohol kills—it kills the alcoholic and it kills unintended victims by the acts of inebriated people. Whatever medical, psychological, or social problem brings the alcoholic to the ED, the underlying problem is alcoholism and the ultimate goal is abstinence. This disease surely progresses if alcoholism is not recognized and if the patient is never given the opportunity to participate in a rehabilitation program.\(^{142}\) The emergency physician can intervene on behalf of the patient and the public.

**KEY CONCEPTS**

- Moderate alcohol consumption is defined as one or two drinks per day in men and one in women.
- Benzodiazepines are the mainstay of treatment for alcohol withdrawal and alcohol withdrawal seizures.
- Inappropriate alcohol consumption or alcohol dependence should be considered in ED patients in almost any clinical situation, including trauma, potential drug-alcohol reactions, pneumonia, cardiomyopathy, new-onset atrial fibrillation, hepatitis, gastrointestinal bleeding, pancreatitis, altered mental status, depression, suicide, magnesium deficiency, and anemia.
- Minor alcohol withdrawal occurs as early as 6 hours and usually peaks at 24 to 36 hours after the cessation of or significant decrease in alcohol intake.
- Major alcohol withdrawal occurs after more than 24 hours and usually peaks at 50 hours (but occasionally takes up to 5 days) after the decline or termination of drinking.
- Delirium tremens is the extreme end of the alcohol withdrawal spectrum and consists of gross tremor, profound confusion, fever, incontinence, frightening visual hallucinations, and mydriasis.
- Not all alcohol-related seizures are alcohol withdrawal seizures.
- "Brief intervention" in the ED can decrease drinking and its long-term consequences.

CHAPTER 184  Substance Abuse

Stephen A. Colucciello and Christian Tomaszewski

■ PERSPECTIVE

The use and abuse of psychoactive substances are not unique to our country or century. People utilized hallucinogenic plants to achieve altered states of consciousness in prehistoric times, and psychoactive substances have been used in all eras and cultures ever since. As Osler remarked, “The desire to take medicine is, perhaps, the great feature which distinguishes man from other animals.” The human cost of substance abuse is high, and deaths secondary to psychoactive substances are common. In the United States, illicit drug use resulted in approximately 17,000 deaths in 2000 (Table 184-1).2

A major barrier to appropriate recognition and treatment of substance abuse is the lack of a precise definition. The American Psychiatric Association defines it as a maladaptive pattern of drug use associated with some manifest harm to the user or others. Physicians have a very difficult time recognizing such abuse when up to 44% of emergency department (ED) patients report underlying chronic pain syndromes.3 Chronic pain may not manifest the typical overt sympathetic changes or physical findings of acute pain. Therefore, emergency physicians constantly walk a tightrope between undertreating legitimate pain and inappropriately rewarding substance abusers with controlled medications.

■ EPIDEMIOLOGY

A variety of stereotypes come to mind when compiling the profile of a substance abuser. These stereotypes pose dangerous traps for the clinician. Physicians are likely to ignore the possibility of drug intoxication in the well-dressed businessman or in those at the extremes of age. Yet children may ingest psychoactive substances they find on coffee tables or floors after parties or passively inhale smoke in rooms where drugs are used. Some parents deliberately give psychoactive substances to their children to calm or abuse them.

Increasing numbers of teens are ingesting dextromethorphan-containing over-the-counter (OTC) products such as Coricidin HBP Cough & Cold tablets.6 These are known on the streets as Tri-C, Red Devils, Red C, Red Box, or Skittles. Other dextromethorphan compounds include cough medicines, such as NyQuil or Robitussin DM, which provide the sought-after high known as the “robo-buzz.” Teens abusing such preparations may present to the ED with anticholinergic syndromes and demonstrate tachycardia, hypertension, mydriasis, somnolence, or agitation.7 Adolescents may also abuse medication used to treat obsessive-compulsive disorder and attention deficit/hyperactivity disorder. Methylphenidate has been a particular concern. Tablets can be abused orally, or they can be crushed and the powder injected or snorted. Despite its abuse potential, experts disagree regarding the extent to which methylphenidate is diverted from therapeutic use to abuse in preteens and adolescents.8

The elderly also abuse substances, and geriatric patients may suffer new-onset psychosis as a result of sympathomimetic abuse or drug withdrawal. Drug use is frequent among pregnant women, resulting in both maternal and fetal morbidity. Up to 7% of women delivering babies have urine toxicology screens that are positive for illicit drugs.9 Manifestations of abuse may be acute, as in abruptio placentae or premature birth, or insidious, producing growth retardation and birth defects. Drug problems are more prevalent among the disadvantaged minority and lower socioeconomic groups. As a result, these groups bear the brunt of drug-related problems, such as incarceration, acquired immunodeficiency syndrome, and tuberculosis.

The Drug Alert Warning Network (DAWN), sponsored by the Substance Abuse and Mental Health Services Administration Office of Applied Studies, collects data from hospital EDs and medical examiners that include drug-related visits or deaths. The data consist of patients who abuse illegal drugs or use legal substances for a nonmedical purpose. According to DAWN, the drugs of misuse or abuse most commonly involved in deaths include cocaine, opiates/opioids, antidepressants, benzodiazepines, and miscellaneous (anxiolytics, sedatives, and hypnotics).10

For 2005, DAWN estimates that 816,696 ED visits involved an illicit drug: Cocaine was involved in 448,481, marijuana in 242,200, heroin in 164,572, and stimulants (including amphetamines and methamphetamine) in 138,950 ED visits. Other illicit drugs (phencyclidine [PCP], Ecstasy, and γ-hydroxybutyric acid [GHB]) were much less frequent.11 In addition, 598,542 ED visits involved nonmedical use of prescription or OTC pharmaceuticals or dietary supplements, an increase of 24% between 2004 and 2005.12 The majority of these visits (55%) involved multiple drugs. Benzodiazepine abuse increased 19%, opiate/opioid abuse increased 24% overall, and methadone abuse-related visits increased by 29%. Among the central nervous system agents, opiate/opioid analgesics accounted for a third of all ED visits, and oxycodone products, hydrocodone products, and methadone were implicated in more than 130,000 ED visits.
